Answer: D. Nonobese patients form a subgroup with a different disease, more similar to type 1 diabetes. Young people with maturity-onset diabetes often have an autosomal dominant inheritance, are nonobese, and have a relatively mild disease course.

118.3. A 56-year-old man with a 10-year history of type 2 diabetes and poor glucose control (HbA\textsubscript{1c} = 10.7%) complains of constant burning pain in both feet. Which agent would be most appropriate to start in this patient for initial management of his symptoms?
A. Aspirin, 325 mg PO daily
B. Carabamazepine, 200 mg tid
C. Naproxen, 500 mg bid
D. Oxycodone/acetaminophen, 5/325 mg qid
E. Pregabalin, 600 mg daily

Answer: E. Pregabalin in a dose of 600 mg daily gives pain relief in approximately 50% of patients with diabetic neuropathy. Duloxetine, 60 mg daily, achieves similar results. Gabapentin, 300 mg once a day up to tid, and amitriptyline, 25 mg daily, provide pain relief in approximately 33% of patients.

118.4. A 27-year-old juvenile-onset diabetic is brought by emergency medical services (EMS) for a hypoglycemic coma. Fingerstick glucose level is 30 mg/dL. The paramedics were not able to obtain intravenous (IV) access, and two immediate attempts at IV cannulation failed in the emergency department (ED). What should be the next step in the patient’s management?
A. Albuterol, 2.5 mg nebulized
B. Central venous catheter placement, then D\textsubscript{50}W IV
C. Epinephrine, 1 mg IV
D. Glucagon, 2 mg intramuscularly
E. Peripheral IV catheterization via cutdown and then D\textsubscript{50}W

Answer: D. Intravenous dextrose (25–75 g for adults, 0.5–1 g/kg for children) is preferable but, if unable to obtain IV access, administer glucagon, 1 or 2 mg intramuscularly (IM) or subcutaneously (SC; 0.025–0.1 mg/kg IM or SC in children). Onset of action is 10 to 20 minutes. It is ineffective in cases of glycogen absence, such as alcohol-induced hypoglycemia.

118.5. A 33-year-old juvenile-onset, insulin-dependent diabetic suddenly fainted without prodrome or warning while walking through the ED. Relatives report that diabetes is his only past history. Which of the following findings is most likely?
A. Autonomic neuropathy on later orthostatic testing
B. Fingerstick glucose 27 mg/dL
C. Hemocult-positive stool
D. Positive enzyme-linked immunosorbent assay (ELISA) D-dimer
E. Supraventricular tachycardia on electrocardiogram (ECG)

Answer: B. Hypoglycemia without warning, or hypoglycemia unawareness, is a complication of type 1 diabetes caused by previous hypoglycemic episodes. A single hypoglycemic episode may blunt neurohormonal counterregulatory responses to later hypoglycemic episodes. Risk factors are overaggressive insulin therapy, longer history of diabetes, and autonomic neuropathy, which usually causes orthostasis on first standing or after being upright in a static position. These patients may become abruptly unarousable without warning.
118.6. A 47-year-old man presents with hypoglycemia. He is a known type 2 diabetic on glyburide. Fingerstick glucose is 27 mg/dL. Twenty minutes after two ampules (50 g) of dextrose, his glucose level is 29 mg/dL. Which of the following agents is indicated?
A. Adenosine  
B. Epinephrine  
C. Glucagon  
D. Hydrocortisone  
E. Octreotide

**Answer:** E. A patient with hypoglycemia from sulfonylureas, in addition to standard glucose replacement, frequently requires treatment with an agent to inhibit further insulin release, such as octreotide (a somatostatin analogue). Sulfonylureas are insulin secretagogues.

118.7. What is the most important determinant of mental status in a patient with diabetic ketoacidosis (DKA)?
A. Acidemia  
B. Calcium level  
C. Glucose level  
D. Osmolarity  
E. Potassium level

**Answer:** D. The hyperosmolarity produced by dehydration and hyperglycemia is the most important determinant of mental status during an episode of DKA.

118.8. A 73-year-old male patient presents with a draining sore on the bottom of his foot. He is noted to have a 3 × 4-cm ulcerated, malodorous lesion on his plantar foot, with surrounding erythema. Which antimicrobial agent should be included as part of the management of this infection?
A. Cefazolin, 1 g qid  
B. Ceftriaxone, 1 g every 24 hours  
C. Levofloxacin, 500 mg every 24 hours  
D. Metronidazole, 500 mg qid  
E. Piperacillin/tazobactam, 3.375 g qid

**Answer:** E. Piperacillin/tazobactam and vancomycin are considered the first-line agents for management of complicated diabetic foot infections.

118.9. A 43-year-old patient is brought to the ED with altered mental status. Other past history is unavailable, there are no signs of trauma, and the physical examination is normal except for the patient’s mental status. Laboratory assessment reveals the following: Sodium = 132 mEq/L  
Potassium = 3.0 mEq/L  
Chloride = 82 mEq/L  
Bicarbonate = 36 mEq/L  
Creatinine = 1.4 mg/dL  
Blood urea nitrogen (BUN) = 26 mg/dL  
Urine ketones—trace positive  
Arterial blood gases (ABG)

PO$_2$ = 90 mm Hg  
Pco$_2$ = 30 mm Hg  
PH = 7.49

What additional finding is the most likely?
A. Elevated glucose level  
B. Elevated iron level  
C. Elevated salicylate level  
D. Evidence of toluene ingestion  
E. History of alcohol abuse

**Answer:** E. The finding of alkalemia with ketoacidosis should prompt the consideration of alcoholic ketoacidosis, in which the acidosis is counterbalanced by alkalosis from severe nausea and vomiting. This may also be seen with DKA but is less likely.

118.10. What percentage of cases of DKA occur in patients whose diabetes was previously undiagnosed?
A. 10%  
B. 25%  
C. 50%  
D. 75%  
E. 90%

**Answer:** B. 25%.

118.11. A 28-year-old juvenile-onset diabetic presents in DKA. Laboratory assessment reveals a sodium level of 130 mEq/L and serum glucose level of 700 mg/dL. What is the approximate total serum sodium value?
A. 125 mEq/L  
B. 130 mEq/L  
C. 135 mEq/L  
D. 139 mEq/L  
E. 144 mEq/L

**Answer:** D. The true value of sodium may be approximated by adding 1.6 mEq/L to the reported sodium value for every 100-mg/dL glucose over the norm.

118.12. A 31-year-old insulin-dependent diabetic presents in DKA. His reported serum potassium level is 5 mEq/L, with a pH of 6.90. What is his corrected potassium level value?
A. 2 mEq/L  
B. 2.5 mEq/L  
C. 3 mEq/L  
D. 3.5 mEq/L  
E. 4 mEq/L

**Answer:** A. The effect of acidosis on the serum potassium can be corrected by subtracting 0.6 mEq/L from the laboratory potassium value for every 0.1 decrease in pH noted on the ABG analysis. For this patient, assuming a normal pH of 7.40,

\[
7.40 - 6.90 = 0.5 \text{ (five } 0.1 \text{ pH increments)}
\]

\[
5 \times 0.6 = 3 \text{ mEq/L correction factor}
\]

118.13. Which of the following statements regarding the laboratory evaluation of DKA is true?
A. Amylase levels maintain their sensitivity for detecting pancreatitis.  
B. Creatinine levels may be falsely elevated.  
C. Hypertriglyceridemia is unusual.  
D. Leukocytosis is often present in the absence of infection.  
E. True magnesium levels may be estimated by a conversion factor.

**Answer:** B. Serum creatinine levels may be falsely elevated if measured by autoanalyzer. No conversion factor exists for estimating magnesium. Leukocytosis typically parallels the degree of ketosis. A bandemia, however, indicates the presence of infection, with a sensitivity of 100% and specificity of 80%. Elevated triglyceride levels are seen routinely. Elevated amylase levels (salivary) are routinely seen; however, lipase maintains its sensitivity for pancreatitis.
118.14. Alcoholic ketoacidosis accounts for what percentage of all cases of ketoacidosis?
A. 10%
B. 20%
C. 30%
D. 40%
E. 50%
Answer: B. Ketoacidosis may also develop with fasting in the third trimester of pregnancy and in nursing mothers who do not eat well.

118.15. A 26-year-old known diabetic presents with altered mental status. EMS reports a fingerstick glucose of 750 mg/dL. The patient vomited once en route. The physical examination is remarkable for a comatose patient with the following vital signs—respiratory rate, 30 breaths/min; heart rate, is 140 beats/min; blood pressure, 85/40 mm Hg. Which of the following should be the first intervention?
A. Dopamine, 10 µg/kg/min
B. Endotracheal intubation
C. Isotonic fluid bolus, 20 mL/kg
D. Regular insulin 0.1 units/kg IV
E. Sodium bicarbonate IV
Answer: B. The comatose DKA patient, especially if vomiting, requires intubation. Hyperventilation should be rapidly initiated to prevent worsening acidosis. Isotonic fluid resuscitation, insulin bolus and infusion, and meticulous attention to electrolyte management must follow.

118.16. What is the half-life of regular insulin when administered intravenously?
A. 3–10 minutes
B. 10–15 minutes
C. 15–20 minutes
D. 20–25 minutes
E. 25–30 minutes
Answer: A. With a half-life of only 3 to 10 minutes, regular insulin requires an infusion rather than intermittent bolus therapy for optimal effect.

118.17. A patient with severe DKA is treated with fluid resuscitation and an insulin infusion. Six hours later, the patient develops confusion, disorientation, and hypercarbia from altered respiratory muscle performance. A repeat serum glucose level is 193 mg/dL. Which of the following treatments is most appropriate?
A. Calcium replenishment
B. Magnesium replenishment
C. Phosphorus replenishment
D. Potassium replenishment
E. Sodium bicarbonate replenishment
Answer: C. Phosphorus levels may fall dramatically after initiation of standard DKA therapy. Hypophosphatemia may cause a left shift in the hemoglobin desaturation curve, depressed myocardial and respiratory muscle function, hemolysis, thrombocytopenia, platelet dysfunction, confusion, and disorientation. Cerebral edema would be in the differential diagnosis because it also occurs in the 6- to 10-hour range after initiating therapy.

118.18. Which of the following is not associated with cerebral edema after DKA?
A. Bicarbonate therapy
B. Blood glucose level > 350 mg/dL
C. Elevated BUN level
D. Hypocarbia
E. Onset 6 to 10 hours after initiation of therapy
Answer: A. B. Clinically evident cerebral edema does not usually occur unless the blood glucose level is less than 250 mg/dL and insulin is being used. The other listed factors are associated with this syndrome.

118.19. Which of the following may be associated with or cause the hyperglycemic hyperosmolar state (HHS)?
A. All of these
B. Anion gap metabolic acidosis
C. Chlorpropamide use
D. Choreoathetosis and segmental myoclonus
E. Confusion with depressed sensorium from hypoglycemia
Answer: A. HHS may be associated with many drugs and illnesses. Symptoms range from lethargy to focal neurologic changes and seizure or coma. Initial differentiation from hypoglycemic coma may be difficult until serum glucose levels are checked. Metabolic acidosis is not uncommon and may yield an elevated anion gap—lactic acidosis, starvation, and retention of inorganic acids. HHS may occur in nondiabetics after burns or peritoneal hemodialysis.

118.20. A 69-year-old patient presents with new-onset seizures, serum glucose level of 850 mg/dL, and serum osmolarity of 340 mOsm/L. His past history is remarkable for chronic renal insufficiency resulting from hypertension. His only current medications are amlodipine and furosemide. Which of the following statements regarding the patient’s condition is true?
A. Emergent dialysis is indicated.
B. Furosemide may have precipitated this event.
C. Heparin has no therapeutic role.
D. Heparin is contraindicated in cases of renal insufficiency.
E. Phenytoin is indicated.
Answer: B. Regardless of the cause, the management of the hyperosmolar hyperglycemic state (HHS) centers on aggressive fluid management and low-dose insulin. Phenytoin is contraindicated in hyperosmolar hyperglycemic nonketotic coma (HHNC) because of its impairment of endogenous insulin release and ability to precipitate HHNC. Low-dose heparin may be indicated to lessen the risk of thrombosis. Furosemide is one of many drugs that may precipitate HHNC.
CHAPTER 119
Rhabdomyolysis
Ram Parekh

PRINCIPLES
Background
Rhabdomyolysis is a potentially life-threatening condition characterized by the breakdown of skeletal muscle and the release into the circulatory system of intracellular contents, including creatine kinase, aspartate transaminase, lactate dehydrogenase, aldolase, the heme pigment myoglobin, and electrolytes. The severity of illness ranges from asymptomatic elevations in serum muscle enzyme levels to life-threatening electrolyte imbalances and acute renal failure.

A healthy 70-kg man has approximately 28 kg of muscle. Skeletal muscle is 80% water and 20% protein, accounting for about half of the total body protein stores, and is the largest organ in the human body.

Physiology
Even at rest, muscle function requires a large amount of adenosine triphosphate (ATP). ATP generation by muscle accounts for 30% of the body’s oxygen consumption at rest and up to 85% at extremes of physical activity. Resting muscle uses fatty acids for ATP generation. With activity, muscle draws on stored ATP for the first 8 seconds of activity, using the phosphagen (creatine phosphate) stores for the next 10 to 15 seconds. Finally, muscle depends on anaerobic glycogen metabolism to lactate for enough ATP and for an additional 30 to 40 seconds of activity. Aerobic ATP production provides the bulk of the energy needed for muscle activity, but it requires oxygen. Glucose, amino acids, and fatty acids are incorporated into the Krebs cycle to produce much larger quantities of ATP by energy-rich compounds, such as the reduced forms of nicotinamide adenine dinucleotide and flavin adenine dinucleotide.

Myoglobin, like hemoglobin, binds and releases oxygen and delivers it to active skeletal muscle. Unlike hemoglobin, myoglobin’s ability to deliver oxygen is unaffected by pH, resulting in a relatively increased affinity for oxygen in comparison to hemoglobin and delivery of oxygen to cellular mitochondria at low partial pressures of oxygen.

The integrity of muscle cells is dependent on healthy cell membranes, which rely on ATP for proper membrane ion pump function. The sarcolemma, a thin membrane that encloses striated muscle fibers, contains numerous pumps that regulate electrochemical gradients. Under normal physiologic conditions, the sodium-potassium–adenosine triphosphatase (Na+,K+-ATPase) pump, located in the sarcolemma, maintains intracellular sodium concentrations of 10 mEq/L and intracellular potassium concentrations of 150 to 160 mEq/L. It achieves this by actively transporting sodium from the interior of the cell to the exterior, thereby making the interior of the cell more negative by the efflux of net positive charge—three sodium ions pumped out per two potassium ions pumped in. This electrical gradient pulls sodium to the interior of the cell through a separate channel in exchange for calcium, effectively removing calcium from the cytoplasm. Low intracellular calcium levels are also maintained by an active calcium exchanger (Ca2+-ATPase pump) that promotes calcium entry into the sarcoplasmic reticulum and mitochondria. As their names indicate, these ATPase pumps depend on ATP as a source of energy.

Under normal physiologic conditions, the concentration of free ionized calcium in the extracellular space is approximately 10,000 times greater than that in the intracellular space. The high concentration of free calcium in the extracellular pool compared with the intracellular compartment and the resulting large electrochemical force on Ca2+ are particularly convenient to its role as an intracellular regulator. Even minor changes in the permeability of the plasma membrane to calcium will produce significant fluctuations in the cytosolic concentration, with potentially unfavorable consequences for the integrity of the cell.

Several transmembrane proteins exist to regulate calcium homeostasis. The plasma membrane transmembrane proteins are the energy-consuming Ca2+ channels, Na+-Ca2+ exchangers, and Ca2+-ATPase pumps. The last removes Ca2+ from the intracellular space by transporting Ca2+ out of the cytosol into the extracellular space, as well as into the sarcoplasmic reticulum. Plasma membrane Ca2+ channels bring Ca2+ into the cytosol when activated at the neuromuscular junction. Na+-Ca2+ exchangers are complicated in that the direction of ion movement depends on the chemical and electrical gradients of each ion within the cell, which vary according to the contractile state of the myocyte (Fig. 119.1).

Pathophysiology
Although the causes of rhabdomyolysis are diverse, the pathogenesis appears to follow a final common pathway—increased cytoplasmic calcium concentration, leading to myocyte destruction, with the release of muscle components into the circulation. There are two primary mechanisms whereby calcium pathologically accumulates in the cell, direct cell membrane damage and ATP depletion.

Membrane damage from trauma and genetic or biochemical factors results in a massive influx of extracellular calcium into the cytoplasm driven by electrical and chemical gradients. ATP depletion results in failure of cellular transport and increased permeability to sodium ions. Any event that increases cytosolic sodium concentrations, whether from increased membrane permeability and inward Na+ traffic or decreased ATP-dependent pump removal of intracellular Na+, results in increased Na+-Ca2+ ion exchanger function and increased cytosolic calcium concentrations. ATP depletion results in dysfunction of energy-dependent ion pumps, such as Na+,K+-ATPase and Ca2+-ATPase in the sarcolemma. Na+,K+-ATPase pump dysfunction leads to increased intracellular Na+, causing a temporary increase in Na+-Ca2+ exchanger function and resultant increase in intracellular Ca2+. The Na+-Ca2+ exchanger requires ATP, however, and continued activity of the Na+-Ca2+ exchanger further depletes the cell of ATP, leading to increased Ca2+-ATPase dysfunction and rising intracellular Ca2+ levels. The sarcoplasmic reticulum and mitochondria are also equipped with these same energy-dependent transmembrane calcium transport...
mechanisms (Ca\(^{2+}\)-ATPase) as well as an ATP-dependent Ca\(^{2+}\) uniporter, further exacerbating the cell's inability to remove intracellular Ca\(^{2+}\) in the low-energy conditions resulting from rehombdomyolysis.

An abrupt increase in cytoplasmic Ca\(^{2+}\) leads to a corresponding increase in mitochondrial Ca\(^{2+}\) because the mitochondria serve as the Ca\(^{2+}\) safety net. In addition to triggering apoptotic cell death by upregulating expression of proapoptotic factors, this mitochondrial Ca\(^{2+}\) overload leads to dysfunction of oxidative phosphorylation through structural and functional alterations, disrupting ATP production and further worsening the ATP debt and intracellular homeostasis of Ca\(^{2+}\).

Increased mitochondrial Ca\(^{2+}\) also leads to increased production of reactive oxygen species (ROS), which are a broad group of chemical substances that include free oxygen radicals (O\(_2^•\), OH\(^•\)) and powerful oxidants (hydrogen peroxide, nitric oxide) that lead to free radical production. Free radicals carry extra unpaired electrons (e\(^•\)) that have a strong tendency to pair off, causing oxidation by extracting electrons from other chemical species. Under normal physiologic conditions, 2% to 5% of oxygen consumed by the mitochondria is transformed during electron transport to ROS that are neutralized by endogenous antioxidants such as glutathione. When the antioxidant capacity of the endogenous system is overwhelmed during times of intense, sustained physical activity or illness, so that rhabdomyolysis results, a condition termed oxidative stress ensues. The resulting ROS-induced destruction of lipids and proteins injures the structure of membranes as well as DNA with mutations, leading to disruptions in cellular architecture and mitochondrial respiratory protein integrity. The cumulative effect exacerbates the inability to regulate intracellular Ca\(^{2+}\) homeostasis. Whereas ROS may have adaptive physiologic functions in exercising muscles, significant damage to muscle cells occurs when ROS are triggered by pathologic stimuli. Damage of the sarcoplasmic reticulum and mitochondria results in the release of stored calcium ions into the cytoplasm. The decreased removal of Ca\(^{2+}\) into the extracellular fluid, along with inadequate intracellular storage and increased entry into the cytoplasm, leads to myocytic Ca\(^{2+}\) overload and initiation of the cascade of cellular death.

Calcium-induced activation of proteases, phospholipases, and other proteolytic enzymes degrades the protein structure of myofibrils, cytoskeleton, and membrane composition, leading to further cellular damage. Increased Ca\(^{2+}\) leads to sustained contraction of the myofibrils, resulting in severe ATP depletion in the initial stages while leading to myofibrillar breakdown as rhabdomyolysis progresses. Breakdown of the myofibrillar network hastens the disintegration of the myocyte, whereas high Ca\(^{2+}\) concentrations within the mitochondria arrest cellular respiration and block ATP production.

Diminished ATP production after Ca\(^{2+}\)-mediated activation of degradative cellular enzymes, with large metabolic energy requirements of their own, exacerbates the preexisting energy crisis within already ischemic cells. This process releases free fatty acids and lysophosphates, which cause direct toxic damage to the sarcotema, intracellular organelles, and plasma membrane carrier proteins, effecting increased Ca\(^{2+}\) entry into the cytosol.

Microelectrode studies of intercostal myocytes have shown that the intracellular calcium concentration rises to 1.27 \(\mu\)mol/L after induction of rhabdomyolysis by exhaustive physical exertion compared with 0.12 \(\mu\)mol/L in normal muscles, representing nearly an 11-fold increase in the intracellular calcium concentration. Dantrolene, a known inhibitor of Ca\(^{2+}\) release from the sarcoplastic reticulum, has been shown to lead to an 83% reduction of cytosolic Ca\(^{2+}\) and an improvement in the clinical symptoms of muscle stiffness, rigidity, and pain, highlighting the essential role of increased cytosolic Ca\(^{2+}\) in the pathophysiologic process of rhabdomyolysis.

Rhabdomyolysis results in muscle cell breakdown, with the release of toxic contents into the extracellular space and damage to adjacent capillaries, resulting in local edema, increased compartmental pressures, and regional ischemia, which further induces energy depletion and destroys more capillaries. Circulating leukocytes adhere to these damaged capillaries, become activated, and transmigrate to the site of myocyte injury, where they release ROS and proteolytic enzymes that injure the cell further. In cases in which ischemia is the inciting event (eg, crush syndrome, arterial thromboembolism) of rhabdomyolysis, myocyte destruction primarily takes place during reperfusion (Fig. 119.2).

Rhabdomyolysis is classified into four basic pathophysiologic processes:

1. Impairment of the muscle’s production or use of ATP at the cellular level. ATP concentrations within the cell fall; energy-dependent mechanisms falter, including Na\(^+\),K\(^+\)-ATPase pumps, leading to disruption of chemical gradients, sarcotema and cell membrane compromise, and cell destruction.
2. Disruption in the delivery of oxygen, glucose, and other nutrients to skeletal muscle
3. Increases in metabolic demands beyond the ability of the organism to deliver oxygen and nutrients
4. Direct myocyte damage

Box 119.1 lists the various causes of rhabdomyolysis.

**CLINICAL FEATURES**

The clinical presentation of rhabdomyolysis is variable because of its many causes. Its course may be mild and subclinical or it may be severe and life-threatening, depending on the extent of muscle damage and associated complications. It may be evident from the patient’s primary complaint or found incidentally on laboratory evaluation. The identification of rhabdomyolysis in the trauma patient is straightforward, whereas the nontraumatic causes may pose a diagnostic challenge.

Rhabdomyolysis should be suspected in patients who present with altered mentation and risk factors for the development of rhabdomyolysis (eg, intoxication, immobility, drug ingestion, electric shock, neuroleptic malignant syndrome). The presence of acute renal failure without another attributable cause also prompts consideration of rhabdomyolysis.

The classic presentation of rhabdomyolysis includes localizing myalgias, muscle stiffness, cramping, swelling, tenderness, and tea-colored urine. The most frequently involved muscle groups are the thighs, calves, and lower back. Nonspecific constitutional symptoms include malaise, fever, nausea, and vomiting. Unfortunately, most cases do not have characteristic physical signs; up to 50% of patients do not report myalgias or muscle weakness,
Fig. 119.2. Pathophysiology of rhabdomyolysis. Ca\(_c\), cytosolic [Ca]; Ca\(_m\), mitochondrial [Ca].

Despite serologically proven rhabdomyolysis, children with rhabdomyolysis may lack many of the classic symptoms; muscle pain and weakness occur in most pediatric patients, but reports of dark urine have been found to be as low as 5%.

History by first responders or witnesses can be helpful, especially when the patient has an altered mental status. In these cases, the physical examination and high clinical suspicion become increasingly important. Findings may include extremity swelling, tenderness, motor weakness, sensory deficits, pain with passive range of motion, and overlying skin changes (particularly in cases of limb ischemia). Muscle swelling may only be evident after resuscitation and rehydration with intravenous (IV) fluids.

**Complications**

**Early Complications**

**Compartment Syndrome.** Most skeletal muscles are encased in compartments formed by bones, fascia, and other structures. The massive influx of calcium and sodium in rhabdomyolysis leads to the accumulation of large amounts of extracellular fluid in the muscle cells, causing local edema and raised intracompartmental pressures, further leading to increased muscle ischemia. Prolonged ischemia and infarction of muscle tissue can lead to replacement of muscle tissue with inelastic fibrous tissue, resulting in severe contractures (Volkman’s contracture). Intrapartmental pressures above 50 mm Hg or sustained pressures of more than 30 mm Hg during a maximum 6-hour period are indications for fasciectomy. Patients with rhabdomyolysis from traumatic compartment syndrome are at high risk of developing acute kidney injury, with concomitant illicit drug or alcohol use and ischemic injuries increasing the odds of injury.

**Electrolyte Disorders and Acidosis.** Potassium release by damaged muscle leads to potentially lethal hyperkalemia, the most serious complication of rhabdomyolysis. Most potassium, 98%, is found in the intracellular space; 60% to 70% of the total cellular mass of the human body consists of skeletal muscle. Therefore, necrosis of as little as 100 g of muscle mass could increase the serum potassium level by 1.0 mEq/L. For comparison, the average 45-year-old man has a total body muscle mass of approximately 30 kg. Acidemia contributes to hyperkalemia and can be exacerbated by oliguria. The resulting fluid sequestration or myoglobin-induced kidney injury reduces the kidney’s ability to excrete acid. Metabolic acidosis is also induced by the release of organic acids (eg, lactic acid, uric acid, sulfur-containing proteins).

The disruption of muscle cells releases large amounts of phosphoric components into circulation, leading to hyperphosphatemia and ectopic calcification, typically depositing in necrotic tissue. Calcium phosphate crystal deposition in damaged muscle can lead to early-phase hypocalcemia, with potentially fatal dysrhythmias. Hyperkalemia coupled with hypocalcemia predisposes patients to malignant dysrhythmias. Furthermore, excessively high phosphate levels shut down the 1α-hydroxylase enzyme of the kidneys through negative feedback, decreasing production of the active form of vitamin D, further reducing calcium absorption from the gut and contributing to early hypocalcemia. Late in the course of rhabdomyolysis, the calcium initially deposited in the cytoplasm of necrotic muscle cells can mobilize and reenter the plasma, resulting in late hypercalcemia.
**BOX 119.1**

**Causes of Rhabdomyolysis**

**PROLONGED IMMOBILIZATION**
- Prolonged immobilization can cause rhabdomyolysis by pressure on gravity-dependent body parts. This pressure-related phenomenon may be enhanced by the underlying cause of the immobilization (eg, drugs or trauma).

**EXCESSIVE MUSCLE ACTIVITY**
- ATP depletion from excessive muscle activity leads to a mismatch of cellular energy needs and ATP supply. This leads to malfunction of ATP-dependent cellular membrane ion pumps, net influx of ionized calcium, and subsequent rhabdomyolysis. Exertion-related cases of rhabdomyolysis have been reported in sporadic and prolonged muscle activity of high and low intensity.

**MUSCLE ISCHEMIA**
- ATP production is limited by interruption of blood perfusion of any cause to muscle tissue, including arterial occlusion, carbon monoxide poisoning, and external compression. Muscle cell hypoxia leads to muscle damage in as little as 2 hours, with irreversible anatomic and functional changes within 4 hours and muscle necrosis in as little as 6 hours.

**TEMPERATURE EXTREMES**
- Extremes of temperature are known to cause rhabdomyolysis by sarcolemma disruption. The physiologic concept of thermal maximum describes the core temperature and duration at which human cells break down. A core body temperature of 42°C (107.6°F) for more than 45 to 60 minutes leads to cellular damage. Heat stroke, neuroleptic malignant syndrome, and malignant hyperthermia are conditions known to lead to excess heat and muscle breakdown. Similarly, hypothermia causes sarcolemma membrane dysfunction below critical temperatures necessary for membrane protein structural integrity. Rhabdomyolysis has been attributed to therapeutic hypothermia in a post–cardiac arrest trauma victim.13

**ELECTRICAL CURRENT**
- Muscle sarcolemma is directly injured by electrical current–induced membrane permeability (electroporation) and thermal injury; high-voltage electrical injury, including lightning, poses the highest risk. Secondary injury by coagulation of blood in muscle capillary beds may lead to localized muscle ischemia. Rhabdomyolysis has also been seen after cardioversion for refractory ventricular tachycardia and fibrillation.

**ELECTROLYTE ABNORMALITIES**
- Hypokalemia by whatever mechanism can cause rhabdomyolysis. Extracellular potassium leads to localized microvascular vasodilation, and low concentrations can lead to focal muscle vasoconstriction and ischemia, with subsequent muscle injury. Hypophosphatemia may result in rhabdomyolysis in that phosphate groups are needed for ATP-dependent cell functions. Hyponatremia has been reported to cause rhabdomyolysis in endurance athletes14 and in those with psychogenic polydipsia. Hyponatremia may also have direct links to rhabdomyolysis in the absence of other known causative agents.

**ILlicit DRUGS**
- A number of illicit drugs, such as opioids, antipsychotics, benzodiazepines, amphetamines, ecstasy, LSD, and synthetic cannabinoids,15,16 can result in rhabdomyolysis by direct or indirect effects, including immobilization with muscle tissue hypoperfusion and hypoxia, psychomotor agitation, direct myotoxicity, and electrolyte abnormalities, particularly hypokalemia and hypophosphatemia.

**Statin-induced rhabdomyolysis is well documented. Its precise mechanism is not fully known but is hypothesized to be due to membrane instability from inhibition of cholesterol synthesis by hydroxymethylglutaryl–coenzyme A reductase inhibition, impaired intracellular protein messaging from abnormally pufylated proteins, and abnormal mitochondrial respiration from coenzyme Q10 deficiency. Similarly, fibric acid derivatives, which decrease hepatic triglyceride production, have been associated with rhabdomyolysis. Many if not most other classes of prescription medications have been associated with rhabdomyolysis, including the typical and atypical antipsychotics.**

**INFECTIONS**
- Rhabdomyolysis has been reported after infections with bacterial, viral, fungal, and parasitic agents. Sepsis-induced tissue hypoxia, direct bacterial myocyte invasion, decreased glycolytic and oxidative enzyme activity, lysosomal enzyme activation, and endotoxin-related injury have all been implicated as pathogenic mechanisms involved in infectious causes of rhabdomyolysis. Rhabdomyolysis has been found in patients with influenza A and should be considered in patients presenting with marked body aches and weakness during flu season.17 *Legionella* is the most common bacterial cause of rhabdomyolysis. It is unclear if rhabdomyolysis is caused by a common pathway of sepsis-related systemic inflammation or species-specific processes.

**METABOLIC MYOPATHIES**
- Inherited disorders are manifested with enzyme deficiencies in carbohydrate and lipid metabolism or myopathies. These lead to defects in glycolysis, gluconeogenesis, fatty acid oxidation, and mitochondrial cellular respiration. These disorders are typically manifested during childhood and are recurrent.

**CONNECTIVE TISSUE DISORDERS**
- Although rare, cases of rhabdomyolysis have been reported in conditions such as polymyositis, dermatomyositis, and Sjögren’s syndrome.

**RHEUMATOLOGIC DISORDERS**
- Systemic lupus erythematosus, usually associated with mild myositis, has also been reported in a case of fulminant myositis with rhabdomyolysis.

**ENDOCRINE DISORDERS**
- Hypothyroidism has been reported to cause rhabdomyolysis.

**BIOLOGIC TOXINS**
- Snakebite, Africanized bees, wasps18,19 and honey bee envenomations are known to release myotoxic agents causing rhabdomyolysis.

**OTHER AND UNKNOWN CAUSES**
- Case reports have documented the development of rhabdomyolysis after succinylcholine administration to patients with neuromuscular disorders,20 as well as in some bariatric surgery patients21 and patients undergoing cardiopulmonary resuscitation. Caffeine toxicity from an overdose can also cause rhabdomyolysis.22

**Hypovolemia.** In rhabdomyolysis, fluid moves from intravascular compartments into damaged muscle, causing profound intravascular volume depletion. This shift may exceed 15 L.

**Hepatic Dysfunction.** Large elevations in serum liver enzyme levels may occur after nontraumatic rhabdomyolysis. The cause of this finding is not fully understood, but proteins released by muscle cells have been implicated. However, aspartate transaminase level elevations may also be of skeletal muscle origin. These derangements are generally reversible. Pre-existing hepatic dysfunction can also potentiate statin-induced rhabdomyolysis.3 7
Late Complications

Myoglobin-Induced Acute Kidney Injury. Experimental evidence has suggested that the mechanisms involved in the pathophysiologic process of myoglobinuric acute renal failure are myoglobin cast formation in the distal convoluted tubules, direct cytotoxic action of myoglobin on the epithelial cells of the proximal convoluted tubules, and intrarenal vasoconstriction and ischemia (Fig. 119.3).

Myoglobin becomes concentrated along the renal tubules and precipitates in acidic urine along with uric acid to form obstructive casts. This process is enhanced by volume depletion and renal vasoconstriction, which reduces blood flow and the glomerular filtration rate (GFR), promoting the accumulation of necrotic epithelial cells into tubular casts and further worsening the GFR. Tubule obstruction occurs at the level of the distal tubule, whereas direct tubule cytotoxicity occurs mainly in the proximal tubules. There remains some controversy about the exact mechanism of renal dysfunction in rhabdomyolysis; some experts believe that casts and tubular obstruction are not the cause but rather the consequence of poor tubular clearance.

When the concentration of myoglobin filtered at the glomerulus exceeds the normal level, tubular cells at the proximal convoluted tubule increase their reabsorption capacity to limit the excretion of myoglobin into the urine, protecting the kidney from its nephrotoxic effects. At a urine pH of 5.6 or lower, myoglobin, an iron-containing heme protein, dissociates into free iron (Fe), ferrihemate (Fe-heme complex), and globin inside the proximal tubular epithelial cell. Free hydroxyl radicals are produced when ferrous oxide in the Fe-heme complex is oxidized by molecular oxygen (O2) and when free iron reacts with H2O2. Free iron may also act as a free radical, although its role in rhabdomyolysis-induced renal injury is unclear. Myoglobin itself has been shown to exhibit peroxidase-like enzyme activity. Ferrihemate causes direct nephrotoxic effects along with the resultant increased oxidative stress within the tubular epithelial cell, leading to acute tubular necrosis through lipid, protein, and DNA peroxidation. More recent evidence has argued against free iron’s role in oxidative stress–induced renal injury and emphasized the role of ferrihemate-induced lipid peroxidation in cell injury.

Fluid shifts and renal dysfunction lead to activation of the renin-angiotensin-aldosterone system and sympathetic nervous system and production of vasoconstricting molecules such as endothelin 1 and vasopressin. There is also decreased production of vasodilatory prostaglandins. Nitric oxide (NO), a potent vasodilatory agent, is known to be responsible for the maintenance of renal blood flow; myoglobin released from damaged muscle may act as a scavenger of NO in the renal microcirculation, itself reduced by NO buffering against oxidant injury by ferrihemate. When NO is overcome by increased myoglobin concentrations, the kidney is deprived of the ability to autoregulate organ blood flow and maintain adequate perfusion in times of shock. Thus, myoglobin is free to cause damage in proximal tubular epithelial cells (under appropriate acidic conditions), as previously described. Other locally stimulated vascular mediators, such as thromboxane A2, tumor necrosis factor alpha, and prostaglandins, which themselves are byproducts of free radical lipid peroxidation, have also been implicated in the reduction of renal blood flow as a result of endothelial disruption and inflammation, as well as oxidant injury.

Disseminated Intravascular Coagulation. Prothrombotic substances, mainly thromboplastin, released from destroyed muscle cells activate the coagulation cascade. They can lead to the formation of thrombi in the capillary tufts of the glomeruli.

**DIAGNOSTIC TESTING**

**Serum Creatine Kinase**

The definitive diagnosis of rhabdomyolysis is reliably made by serologic testing for creatine kinase (CK). This test can assist the clinician in assessing at-risk patients when historical and examination findings are lacking. Elevated levels of CK are the hallmark of rhabdomyolysis. CK functions as an energy reservoir for ATP: creatine + ATP = creatine kinase + ADP (adenosine diphosphate). CK has a half-life of 1.5 days; its level elevated in the first 12 hours, peaks during the first 3 days, and normalizes at around 5 days after injury. A CK level five times the upper limit of normal (=1000 U/L), without apparent cardiac or brain injury, confirms the diagnosis.

**Serum and Urine Myoglobin**

Myoglobin is a dark red protein composed of globin and a molecule of heme. Its normal function is to supply oxygen to skeletal and cardiac muscle in times of need. The excretion of myoglobin occurs renally. It is initially filtered at the glomerulus and reabsorbed by endocytosis in the convoluted tubules, where it is broken into its component parts, globin and heme, by proteolytic enzymes. As with all other low-molecular-weight proteins, a small amount is excreted in the urine. The normal concentration of myoglobin in the urine is less than 10 µg/L. A normal serum concentration of myoglobin is less than 100 µg/L.

During rhabdomyolysis, myoglobin released by damaged muscle is increasingly filtered at the glomerulus. This leads to an initial increased reabsorptive capacity by glomerular and tubular epithelial cells, developed presumably as a protective response to increased filtered myoglobin. When serum myoglobin concentrations exceed 0.3 mg/L and the renal threshold of 1.0 mg/dL is met, this reabsorptive capacity is overwhelmed, and excess myoglobin appears in the urine. This myoglobin is detected by urine dipstick as positive for blood (Table 119.1).

In the past, the diagnosis of rhabdomyolysis was made by serum myoglobin; however, myoglobin has a serum half-life of only 1 to 3 hours and is completely absent after 24 hours. This
This suggests that age initially sequestered in damaged muscle. Common electrolyte disturbances in patients with rhabdomyolysis include hyperkalemia, hyperphosphatemia, and early hypocalcemia followed by late hypercalcemia. Late hypercalcemia is postulated to be due to the mobilization of calcium that was initially sequestered in damaged muscle.

Hyperuricemia from the release of muscle nucleic acids is especially common in patients with large muscle mass. Metabolic acidosis typically occurs from the generation of organic acids during rhabdomyolysis, which plays a role in cast and uric acid crystal formation, as well as pathologic myoglobin metabolism in tubular epithelial cells. Proteinuria may also be noted because of the detection of the globin component of myoglobin. Urine sediment analysis will show myoglobin casts and dead epithelial cells (see Table 119.1).

### Other Laboratory Findings

Common electrolyte disturbances in patients with rhabdomyolysis include hyperkalemia, hyperphosphatemia, and early hypocalcemia followed by late hypercalcemia. Late hypercalcemia is postulated to be due to the mobilization of calcium that was initially sequestered in damaged muscle.

Hyperuricemia from the release of muscle nucleic acids is especially common in patients with large muscle mass. Metabolic acidosis typically occurs from the generation of organic acids from damaged muscle—namely, lactate and uric acid. Hypoalbuminemia and anemia result from capillary damage and release into the extracellular space.

Both the blood urea nitrogen (BUN) and creatinine (Cr) concentrations increase, but with a characteristic decrease in the BUN/Cr ratio due to large amounts of creatinine released into the serum from damaged muscle. A normal BUN/Cr ratio is 10:1; in rhabdomyolysis, it can be 5:1 or even less. In severe cases, coagulation disorders such as disseminated intravascular coagulation (DIC) can ensue, triggered by the released thromboplastin from damaged tissue.

### Prognostic Tests in Rhabdomyolysis

Most studies evaluating the ability for the CK level to predict renal injury have been retrospective and conducted in admitted patients. In these reports, the degree of CK level elevation has not been found to be a reliable predictor of acute kidney injury, with most showing no correlation or a weak one. One study of admitted pediatric trauma patients did find a correlation between CK levels above 3000 U/L and acute kidney injury. This suggests that age and etiology of rhabdomyolysis may permit the use of CK as a predictor for kidney injury in certain populations.

In one of the only studies of emergency department (ED) patients with rhabdomyolysis, the CK level did not correlate with the primary outcomes of need for dialysis or death at 30 days. However, the estimated glomerular filtration rate (eGFR), calculated as 175 × (Cr/88.4)^-1.154 × (age)^0.203 for males, multiplied by 0.742 for females, did correlate with the primary outcomes, with no patients with an eGFR of less than 60mL/min/1.73 m^2 developing acute kidney injury or dying. Based on the cumulative evidence, I recommend that the CK level should be used as a diagnostic marker for rhabdomyolysis and not as a prognostic indicator of acute renal injury. Once the diagnosis is made, the eGFR can be used to predict renal injury and determine the need for admission; I recommend using a computer application to calculate eGFR from the formula. The degree of creatinine level elevation at the time of admission has been shown to correlate with 30-day mortality rates.

### MANAGEMENT

Management of rhabdomyolysis focuses on treatment of the cause, prevention of renal failure, and management of life- or limb-threatening complications.

### Fluid Replacement and Urine Alkalization

Volume expansion is critical to avoiding myoglobin-induced acute renal failure. Fluid expansion increases renal blood flow and therefore glomerular filtration and urination. Patients with rhabdomyolysis typically present with severe dehydration due to fluid sequestration in the affected skeletal muscles. Several case series, mostly from victims of natural disasters (eg, earthquakes with building collapse), have shown that some degree of intravascular volume contraction is a prerequisite for developing acute renal failure. Because acute renal failure appears to develop in patients with a longer delay to supportive therapy, fluid resuscitation should be instituted early. For victims of mass casualty events with prolonged extrication times, fluid resuscitation should begin before complete extrication.

Although the need for early volume expansion is universally accepted, the composition of the fluid is more controversial, especially regarding the concept of urine alkalization. The principles of urine alkalization have been derived empirically from animal data: (1) myoglobin precipitation is increased in acidic urine; (2) reduction-oxidation (redox) cycling of myoglobin and lipid peroxidation, and thus tubule injury, are inhibited by alkaline urine; and (3) myoglobin induces renal vasoconstriction only in an acidic medium. Myoglobin-induced lipid peroxidation occurs

*Urine tested with dipstick test.

**Normal refers to white or yellow color.

*Food and drugs that can cause red urine include beets, blackberries, rhubarb, food coloring, fava beans, phenolphthalein, rifampin, doxorubicin, deferoxamine, chloroquine, ibuprofen, and methylhyp. Those that cause brown urine include levodopa, metronidazole, nitrofurantoin, iron sorbitol, chloroquine, and methylhyp. Adapted from Bosch X, Poch E, Grau JM: Rhabdomyolysis and acute kidney injury. N Engl J Med 361:62–79, 2009.
Although the precise benefit of alkaline therapy in rhabdomyolysis is unknown, what is known is the impact of large volumes of normal saline on the serum pH. Normal saline contains supraphysiologic concentrations of chloride ions. Massive infusion of normal saline leads to a disproportionate increase in serum chloride concentrations, inducing an iatrogenic metabolic (hyperchloremic) acidosis that exacerbates myoglobin precipitation, tubular obstruction, and risk of hyperkalemia-related complications.

The administration of both normal saline and sodium bicarbonate, especially in patients with metabolic acidosis, may be one approach to fluid resuscitation. If sodium bicarbonate therapy is used, the urine and serum pH and serum bicarbonate, potassium, and calcium levels should be monitored. The urine should be monitored at concentrations several orders of magnitude lower than those that lead to the precipitation of casts in the distal tubules.

The theory of alkalinization has been supported by the discovery that alkalinization inhibits redox cycling of myoglobin and lipid peroxidation. However, the clinical benefits of alkalinization compared with simple saline volume repletion are not firmly established, and sodium bicarbonate therapy has not been proven necessary or superior to normal saline diuresis at increasing urine pH. Comparative studies have been limited by their small sample sizes and variability in the severity of rhabdomyolysis, determined by CK level. They have been further complicated by the administration of multiple therapeutic measures (eg, bicarbonate plus mannitol), making the impact of any one measure difficult to interpret.

Although the precise benefit of alkaline therapy in rhabdomyolysis is unknown, what is known is the impact of large volumes of normal saline on the serum pH. Normal saline contains supraphysiologic concentrations of chloride ions. Massive infusion of normal saline leads to a disproportionate increase in serum chloride concentrations, inducing an iatrogenic metabolic (hyperchloremic) acidosis that exacerbates myoglobin precipitation, tubular obstruction, and risk of hyperkalemia-related complications.

The administration of both normal saline and sodium bicarbonate, especially in patients with metabolic acidosis, may be one approach to fluid resuscitation. If sodium bicarbonate therapy is used, the urine and serum pH and serum bicarbonate, potassium, and calcium levels should be monitored. The urine should be monitored at concentrations several orders of magnitude lower than those that lead to the precipitation of casts in the distal tubules.
adequate diuresis is not achieved or if the osmolal gap rises above be frequently monitored; treatment should be discontinued if mannitol is used, the plasma osmolality and osmolal gap should therapy, may be beneficial to relieve compartment pressures. If ity, a condition known as osmotic nephrosis. However, mannitol has not been shown to be more beneficial than fluid expansion alone, and no randomized controlled trials have shown any beneficial effect. Large accumulated doses of mannitol may be detrimental by causing renal vasoconstriction and tubular toxicity, a condition known as osmotic nephrosis. However, mannitol therapy, may be beneficial to relieve compartment pressures. If mannitol is used, the plasma osmolality and osmolar gap should be frequently monitored; treatment should be discontinued if adequate diuresis is not achieved or if the osmolar gap rises above 55 mOsm/kg.

**Furosemide**

Loop diuretics also increase urinary flow, but no study has shown a clear benefit in patients with rhabdomyolysis. Therefore, they are not recommended as prophylaxis against myoglobin-induced renal failure.

**Acetazolamide**

Carbonic anhydrase inhibitors for urine alkalinization have been used when bicarbonate therapy results in metabolic alkalosis with persistent acidic urine. Acetazolamide has theoretic advantages because it induces bicarbonate diuresis, with restorative effects on acid-base status from natriuresis. Case reports have shown potential benefit, but this has not been confirmed experimentally or clinically and cannot be recommended at this time.

**Experimental Therapies**

Antioxidants such as glutathione and vitamin E analogues have shown promise in experimental animal models of myoglobin-induced oxidant injury and may have a future role in management. Grape seed proanthocyanidin extract has been shown to have renoprotective effects in rat models of rhabdomyolysis. The xanthine oxidase inhibitor, allopurinol, is being studied as a prophylactic agent in nonathletes at risk for exertional rhabdomyolysis.

**Renal Replacement Therapy**

As with non–rhabdomyolysis-related causes of renal failure, the indications for emergent dialysis or filtration remain uncorrectable metabolic acidosis, life-threatening hyperkalemia and other electrolyte disturbances despite medical management, manifestations of uremia, and anuria or oliguria, despite volume expansion with complications related to fluid overload. Fluid overload is particularly problematic when it results in pulmonary edema or in patients with poor cardiac reserve. Conventional hemodialysis does not filter myoglobin effectively because of its large size. Renal replacement therapy (RRT) is indicated, with intermittent hemodialysis to correct electrolyte abnormalities rapidly. Continuous venovenous hemofiltration or hemodiafiltration has shown promise for the removal of myoglobin in case reports, although outcome data are lacking. Continuous renal replacement therapy (CRRT) may be more desirable than intermittent RRT because of the theoretic hemodynamic and homeostatic benefits of continuous versus intermittent therapy. However, three small, poorly designed randomized trials of CRRT have failed to show a decrease in mortality, despite more rapid removal of myoglobin and improvement in electrolyte, BUN, and creatinine levels. The need for RRT in the acute setting of rhabdomyolysis does not predict the need for long-term hemodialysis.

**DISPOSITION**

The need for fluid resuscitation in rhabdomyolysis and close monitoring of renal function and electrolytes require hospitalization in most cases. Observation stays can be considered in milder cases but more complicated cases warrant admission to a monitored setting until resolution of metabolic and hemodynamic perturbations. The type of hospital bed is contingent on the cause of rhabdomyolysis, presence of comorbidities, and severity of illness at presentation. Fluid resuscitation should generally be initiated at CK levels more than five times the upper limit of normal (typically, 1000 IU/L) and should be continued until levels trend down and drop below this level.

**Prognosis**

Rhabdomyolysis, when recognized and treated early, carries an excellent prognosis. With the exception of hyperkalemia-related death or the rare complication of DIC, acute kidney injury is the most serious complication of rhabdomyolysis, regardless of cause. Of patients who have acute renal failure, most will recover full renal function when treatment is instituted in a timely fashion. Mortality data for patients with renal failure vary widely in the literature according to the study population, cause, presence of multiple causative agents, and comorbidities; however, long-term survival among patients with rhabdomyolysis and acute renal injury tends to be very good when timely management is provided.
Rhabdomyolysis is generally a benign syndrome, but with potentially fatal complications. Acute renal failure and hyperkalemia are accompanied by high mortality.

Rhabdomyolysis should be suspected in at-risk patients (see Box 119.1) who present with muscle pain or altered mentation. The diagnosis of rhabdomyolysis is confirmed with an elevated serum CK level (>1000 U/L).

In patients with rhabdomyolysis, the degree of CK elevation is not a reliable predictor of risk of acute renal injury.

IV fluid administration should be aimed at maintaining a urine output of at least 300 mL/hr in the average-sized adult patient with rhabdomyolysis. Diuretics have no role in the management of most cases of rhabdomyolysis. Survivability hinges on prompt recognition and resuscitation with a liberal fluid strategy, with or without urine alkalinization.

CHAPTER 119: QUESTIONS & ANSWERS

119.1. Which of the following statements regarding muscle cell physiology and rhabdomyolysis is true?
A. Acute renal failure from rhabdomyolysis is very rare.
B. Hemoglobin has a higher oxygen affinity than myoglobin.
C. The final common pathway of injury in rhabdomyolysis is cell membrane damage.
D. The normal intracellular Na+ concentration is high.
E. The normal intracellular Ca2+ concentration is low.

Answer: E. Normal intracellular concentrations of Na+ are low, creating a negative intracellular environment. This allows more Na+ to enter the cell, which is an important factor in the development of rhabdomyolysis.

119.2. Which of the following statements regarding exertion (exercise)-related rhabdomyolysis is true?
A. Eccentric (lengthening) muscle work is more damaging than concentric.
B. Hypokalemia increases the risk for this syndrome.
C. It is the result of voluntary muscle exertion.
D. It is seen exclusively in untrained athletes.
E. The mechanism is different than after a crush injury.

Answer: A. Exertional rhabdomyolysis is seen in trained and untrained individuals as well as after exercise or situations of involuntary muscle activity (eg, psychoses, seizures, tetany, myoclonus). The mechanism (eg, failure of energy supplies, sarcolemma breakdown, intracellular calcium accumulation, enzyme dysfunction, cellular swelling) is the same. Hypokalemia is a risk factor because a low potassium level limits microvascular dilation and muscle perfusion.

119.3. Which of the following statements regarding drug-induced rhabdomyolysis is true?
A. Cocaine myotoxicity is not related to the degree of intoxication.
B. Colchicine and cyclosporine are myotoxins.
C. Ethanol myotoxicity is potentiated by high carbohydrate intake.
D. Statin myotoxicity is unrelated to state of hydration.
E. The use of the drug ecstasy is not associated with rhabdomyolysis.

Answer: B. Statins, ethanol, cocaine, colchicine, cyclosporine, and many other drugs are myotoxic. Illicit drugs include amphetamine, ecstasy, LSD, and other sympathomimetics. Ethanol is a direct muscle membrane toxin, the drug ecstasy is potentiated by high carbohydrate intake, and statins are myotoxic.

119.4. What is the most common viral cause for rhabdomyolysis?
A. Cytomegalovirus
B. Epstein-Barr virus
C. Herpesvirus
D. Human immunodeficiency virus
E. Influenza virus

Answer: E. Influenza is the most common viral etiology followed by HIV infection and enteroviral infection.

119.5. What is the most common bacterial cause for rhabdomyolysis?
A. Legionella
B. Pseudomonas
C. Salmonella
D. Staphylococcus
E. Streptococcus
Answer: A. Legionella is the bacterium classically associated with rhabdomyolysis in adult patients. The pathogenesis is believed to be due to direct invasion and toxic degeneration of muscle fibers.

119.6. Which of the following electrolyte abnormalities has not been associated with rhabdomyolysis?
A. Hypermagnesemia
B. Hypernatremia
C. Hypocalcemia
D. Hyponatremia
E. Hypophosphatemia

Answer: A. There are no reported cases of hypermagnesemia induced rhabdomyolysis to date.

119.7. A 53-year-old intoxicated alcoholic is brought to the ED by EMS after being found unconscious for an unknown reason. He is now awake but mildly lethargic. He has no complaints of pain or disability. The physical examination is nonfocal. Which of the following statements is true?
A. A CK-MB fraction of 5% would indicate myocardial damage.
B. A negative urine myoglobin level would exclude rhabdomyolysis.
C. His lack of pain complaints would exclude rhabdomyolysis.
D. Hypocalcemia would be expected in the presence of rhabdomyolysis.
E. If rhabdomyolysis were found, normal phosphate level would be reassuring.

Answer: D. Hypocalcemia is the most common electrolyte abnormality after rhabdomyolysis. Hypercalcemia may follow later. Only 50% of patients with serum evidence of rhabdomyolysis have complaints of muscle pain. Likewise, the presence of urine myoglobin reflects the glomerular filtration rate, plasma myoglobin concentrations, urine flow, and plasma myoglobin binding. This test result may be negative, especially late in the course of the process. Hyperphosphatemia is expected, and a normal level raises the suspicion that hypophosphatemia was the cause of the rhabdomyolysis. CK-MB levels of 3% to 5% are often seen and reflect skeletal rather than cardiac muscle damage.

119.8. Which of the following is a proven cornerstone of management for rhabdomyolysis, along with saline hydration?
A. Alkalization
B. Chelation therapy
C. Furosemide
D. Mannitol
E. None of the above

Answer: E. Furosemide is somewhat contraindicated because of its tendency to acidify the urine. Mannitol and alkalization are not proven, although they are often used. Chelation therapy is under investigation.
Thyroid dysfunction (hyperthyroidism and hypothyroidism) arguably represents the most common form of endocrine disorder. Together with adrenal insufficiency, these disease states are often manifested with nonspecific symptoms, such as fatigue and weakness, making them a diagnostic challenge. In their advanced states, classic manifestations develop, rendering each disorder more recognizable. Each disorder is also capable of producing life-threatening symptoms when it is untreated or precipitated by other stressors.

**HYPERTHYROIDISM**

**Principles**

**Background**

Hyperthyroidism is a condition caused by overproduction and increased circulation of thyroid hormone. The disorder runs the spectrum from subclinical hyperthyroidism to thyrotoxicosis, a life-threatening disorder. Thyrotoxicosis is a hypermetabolic condition that results from elevated levels of thyroid hormones—triiodothyronine (T₃) and thyroxine (T₄). This can occur from hormone overproduction (Graves’ disease, toxic multinodular goiter), increased thyroid hormone release from an injured gland (thyroiditis, trauma), or exogenous thyroid hormone (thyrotoxicosis factitia). Most cases of thyrotoxicosis (>80%) are due to autoimmune disease. For the purpose of this discussion, the terms hyperthyroidism and thyrotoxicosis are used interchangeably.

**Anatomy and Physiology**

The normal adult thyroid gland is a highly vascular bilobar organ overlying the anterior trachea (Fig. 120.1). The thyroid’s function is to secrete two iodinated hormones, T₄ and T₃. Only about 20% of circulating T₄ is directly secreted by the thyroid; the remainder is produced by peripheral conversion of T₄ to the more biologically active T₃. The thyroid is the only endocrine gland that stores large quantities of hormone, with enough for a 100-day supply. Hormone production is regulated by a negative feedback loop involving the hypothalamic-pituitary-thyroid axis (Fig. 120.2). As the serum levels of T₄ and T₃ fall, the hypothalamus releases the tripeptide thyrotropin-releasing hormone (TRH), which in turn stimulates the anterior pituitary gland’s release of the polypeptide thyroid-stimulating hormone (TSH) from its thyrotroph cells. TSH then binds to epithelial cells on the thyroid gland, stimulating follicular cells to synthesize and secrete the thyroid hormones T₄ and T₃. TRH release may also result from exercise, stress, malnutrition, hypoglycemia, and sleep.

The function of thyroid hormone is to influence the metabolism of cells by increasing their basal metabolic rate. It has a role in protein synthesis and functions together with other hormones necessary for normal growth and development. Of note, T₃ and T₄ increase the expression and sensitivity of β-adrenergic receptors, dramatically increasing response to endogenous catecholamines.

**Pathophysiology**

T₄ is a prohormone with only mild intrinsic activity; its deiodination produces T₃, the biologically active hormone. More than 99.5% of thyroid hormones are protein-bound in the serum to thyroxine-binding globulin (TBG) and other proteins, rendering them metabolically inactive. As a result, only free T₄ and free T₃ are clinically relevant.

Although iodide is a necessary substrate for thyroid hormone production, excess iodine can have two opposing effects. In the Wolff-Chaikoff effect, excess iodine inhibits the release of thyroid hormone from the gland by blocking iodide trapping and thyroglobulin iodination. This inhibition is transient, typically lasting only a matter of days. Iodide load can induce hyperthyroidism (Jod-Basedow effect) in some patients with multinodular goiter and occult Graves’ disease.

**Graves’ Disease.** Graves’ disease is the most common form of hyperthyroidism in the United States; autoantibodies bind to the TSH receptor and stimulate thyroid hormone production and release. Graves’ disease has a strong genetic relationship, with frequent occurrence in the setting of other autoimmune disorders and positive family history, and 20% of cases have been found to be related to environmental causes, such as smoking.

**Toxic Multinodular Goiter.** Toxic multinodular goiter is the second leading cause of hyperthyroidism in the United States. It is characterized by multiple autonomously functioning nodules, usually in women older than 50 years. The hyperthyroidism in toxic multinodular goiter is milder than Graves’ disease and gradual in onset, but acute presentations can occur when iodine replacement is given to an iodine-deficient individual.

**Toxic Adenoma.** A toxic adenoma is a single hyperfunctioning nodule within the thyroid. It typically affects the same population as toxic multinodular goiter, but is less common.

**Thyroiditis.** Any inflammatory process that results in thyroid gland inflammation can lead to thyroiditis. The initiating process may be autoimmune, drug-induced, infectious, or traumatic. Inflammation leads to follicular cell breakdown, with resultant release of preformed thyroid hormone, causing acute thyrotoxicosis. The most common form of thyroiditis in the United States is Hashimoto’s thyroiditis, an autoimmune disorder characterized by the presence of thyroid antibodies and lymphocytic infiltration of the thyroid gland. Typically, patients present with a painless goiter and hypothyroidism, but some have transient thyrotoxicosis (hashitoxicosis) that may last a few months.

**Silent Thyroiditis.** Painless, or silent, thyroiditis is typified by a small nontender goiter and mild symptoms. It is more common in women than men, with a peak from age 30 to 40 years. It has an autoimmune cause and is seen more commonly in areas of adequate iodine intake.
(2) a hypothyroid state lasting 2 to 3 months; and (3) finally, a euthyroid state by the end of the first postpartum year. Although this triphasic course is classically described, many have only thyrotoxicosis (20%–30%) or hypothyroidism (40%). The recurrence rate in subsequent pregnancy is estimated at 70% in genetically predisposed women; some women have permanent hypothyroidism.4

Subacute Thyroiditis. Subacute thyroiditis (de Quervain’s thyroiditis) is thought to be caused by a viral infection of the thyroid. It is manifested with a viral prodrome—fever, fatigue, myalgias, and pharyngitis—followed by anterior neck pain. Pain may radiate to the jaw, ears, or occipital area. The thyroid is exquisitely tender, and pain can occur with head movement or swallowing. During the acute painful phase, about 50% of patients have symptoms of hyperthyroidism (diaphoresis, palpitations, and tremor) lasting 3 to 6 weeks. These symptoms are usually mild. About one-third of patients will then have hypothyroidism for up to 6 months. Subacute thyroiditis occurs most commonly in the fourth and fifth decades of life and is more common in women.

Suppurative Thyroiditis. Suppurative thyroiditis is a rare but potentially life-threatening infection of the thyroid. Patients present with fever and anterior neck pain, neck swelling, induration, and erythema, as well as dysphonia and dysphagia. Infectious causes are overwhelmingly bacterial (aerobic and anaerobic) and very rarely parasitic, mycobacterial, or fungal.4 Most patients have preexisting thyroid disease and are immunocompromised (eg, AIDS).

Drug-Induced Thyroiditis. Amiodarone contains a high amount of iodine (37%, about 400 times the daily requirement) and, as a result, has a significant effect on thyroid function. It is
estimated that between 5% and 20% of patients treated with amiodarone will develop thyrotoxicosis, higher in areas of iodine deficiency. Two proposed mechanisms have been described, an iodine-induced hyperthyroidism and drug-induced destructive thyroiditis. It is thought that the iodine load may unmask hyperthyroidism in patients with multinodular goiter and subclinical Graves’ disease. More commonly, the cytotoxic effects of amiodarone destroy thyroid cells, resulting in a release of preformed hormone. An exacerbation of the tachyarrhythmia for which the patient is being treated or heart failure is the typical presentation of a patient with thyrotoxicosis related to amiodarone. Other drugs that may induce thyroiditis include interferon alpha, highly active antiretroviral therapies, tyrosine kinase inhibitors, interleukin-2, and lithium. Lithium induces sporadic thyroiditis by direct toxic effects.5

**Factitious Thyroiditis.** Thyrotoxicosis factitia results from the ingestion of thyroid hormone. Most cases involve medical personnel with psychiatric illness who surreptitiously self-administer the medication. Cases of factitious thyrotoxicosis have also been reported in patients taking nutritional supplements that are marketed to improve thyroid function or aid in weight loss. In some cases, these supplements include doses of thyroid hormone beyond that which is typically prescribed, even with the recommended dose.7

**Subclinical Hyperthyroid.** Subclinical hyperthyroid, identified by a low TSH and normal concentrations of free T4 and T3, has recently been identified as a risk factor for cardiovascular morbidity and mortality. These patients have overall increased mortality and are at risk for coronary heart disease, events, and atrial fibrillation.3

**Clinical Features**

**History and Physical Examination**

Hyperthyroidism induces a hypermetabolic state and increases β-adrenergic activity. The resulting clinical manifestations range from vague constitutional symptoms to more organ-specific symptoms (Box 120.1). Variables that affect the severity of disease include age and disease duration and do not necessarily correlate with the degree of biochemical abnormality. Altered mental status and coma typify thyroid storm, the most severe manifestation of disease.

Hyperthyroidism in older adults often manifests in more subtle ways, often asymptomatic or with nonspecific symptoms of weight loss, shortness of breath, and/or dementia. Older adults are more prone to cardiac manifestations and often present with atrial fibrillation; older adults who smoke or have higher circulating thyroid hormone levels appear to have more severe symptoms.3 Thyrotoxic periodic paralysis is manifested as a sudden and profound muscle weakness progressing to flaccid paralysis. It closely resembles familial hypokalemic periodic paralysis. Superior vena cava syndrome and dyspnea can occur as a result of the compression of vascular and tracheal structures by an enlarged thyroid. Dysphagia is common and can be due to compression of the esophagus by an enlarged thyroid gland or dysmotility related to thyrotoxic myopathy.

Ophthalmopathy is a classic finding in Graves’ disease; it is thought to result in a proliferation of orbital fibroblasts differentiating into adipocytes and orbital infiltration of inflammatory cells. Patients subsequently present with diplopia, photophobia, tearing, grittiness, and pain because of corneal exposure, as well as eyelid edema, hyperemia, conjunctival hyperemia, and chemosis.10 Graves’ ophthalmopathy is also associated with restrictive extraocular myopathy, and exophthalmos. As the disease progresses, patients may experience restriction of their upward gaze from infiltration of the inferior rectus muscle and visual loss from optic nerve involvement (compression by inflamed, enlarged orbital contents).10

Physical examination findings of hyperthyroidism depend largely on age (Box 120.2). Younger patients typically present with signs of sympathetic stimulation, whereas older adults often lack the same adrenergic response and present with weight loss and fatigue, more consistent with apathetic hyperthyroidism.11 In Graves’ disease, patients uncommonly have classic pretibial myxedema, in which mucopolysaccharide infiltration of the dermis yields marked thickening of the pretibial skin. These lesions are confluent, painless, reddish raised nodules and plaques over the pretibial area and dorsum of the feet, often described as orange skin. Hyperpigmentation and induration are present, but pitting edema, in which mucopolysaccharide infiltration of the dermis yields marked thickening of the pretibial skin. These lesions are confluent, painless, reddish raised nodules and plaques over the pretibial area and dorsum of the feet, often described as orange skin. Hyperpigmentation and induration are present, but pitting is absent. Pretibial myxedema is almost always associated with Graves’ ophthalmopathy.10

Tachycardia is the most common cardiac finding. Other findings include a widened pulse pressure, bounding peripheral pulses.

**BOX 120.1**

**Symptoms of Thyrotoxicosis**

- Constitutional: Weight loss despite hyperphagia, fatigue, generalized weakness
- Hypermetabolic: Heat intolerance, cold preference, excessive perspiration
- Cardiorespiratory: Palpitations, dyspnea, dyspnea on exertion, chest pains, poor exercise tolerance
- Gastrointestinal: Nausea, vomiting, diarrhea, dysphagia
- Neuropsychiatric: Anxiety, restlessness, hyperkinesia, emotional lability, confusion, insomnia, poor attention
- Neuromuscular: Myopathy, myalgias, tremor, proximal muscle weakness (difficulty getting out of a chair or combing hair)
- Ophthalmologic: Tearing, irritation, wind sensitivity, diplopia, foreign body sensation
- Thyroid gland: Neck fullness, dysphagia, dysphonia
- Dermatologic: Flushed feeling, hair loss, pretibial swelling
- Reproductive: Oligomenorrhea, amenorrhea, menometrorrhagia, decreased libido, gynecomastia, erectile dysfunction, infertility

**BOX 120.2**

**Physical Findings in Thyrotoxicosis**

- Vital signs: Tachycardia, widened pulse pressure, bounding pulses, fever
- Cardio: Hyperdynamic precordium, systolic flow murmur; prominent heart sounds, systolic rub (Means-Lerman scratch), tricuspid regurgitation, atrial fibrillation, evidence of heart failure
- Ophthalmologic: Widened palpebral fissures (stare), lid lag, globe lag, conjunctival injection, periorbital edema, proptosis, limitation of superior gaze
- Neurologic: Fine tremor, hyperreflexia, proximal muscle weakness
- Psychiatric: Fidgety, emotionally labile, poor concentration
- Dermatologic: Warm, moist, smooth skin; rosy cheeks, blushing face; fine brittle hair; alopecia, flushed facies; palmar erythema; hyperpigmented pretibial plaques, nodules, or induration that is nonpitting; enecholyisis (Plummer’s nails, separation of the distal portion of the fingernail from the nail bed)
- Neck: Diffuse symmetric thyroid enlargement, sometimes with a bruit and palpable thrill; thyroid with multiple irregular nodules or a prominent single nodule; tracheal deviation, venous prominence with arm elevation (Pemberton’s sign)
and, rarely, a friction rub heard along the left sternal border (Means-Lerman scratch). Atrial fibrillation is more common in older adults, with an incidence of 13% in patients older than 65 years with hyperthyroidism. Dilated cardiomyopathy may develop as a complication of a high cardiac output state. Patients can also develop primary pulmonary hypertension, sometimes associated with tricuspid regurgitation and right-sided heart failure.

Increased activity at the sympathetic innervation of the eyelids leads to widening of the palpebral fissures, resulting in the characteristic stare and lid lag of thyrotoxicosis. Most hyperthyroid patients have an enlarged thyroid gland. Enlargement is common in patients with toxic multinodular goiter or Graves’ disease. However, many older adults with Graves’ disease have nonpalpable thyroids. Retrosternal enlargement can occur, making detection difficult while causing the obstructive symptoms discussed earlier. Facial and neck vein engorgement can be elicited when arms are elevated above the head, Pemberton’s sign.

Negligible to moderate thyroid enlargement can be seen in patients with Hashimoto’s or painless thyroiditis (postpartum and sporadic). The thyroid gland in subacute thyroiditis is slightly enlarged and exquisitely tender. The addition of overlying erythema or warmth is seen in suppurative thyroiditis. The absence of thyroid enlargement should suggest exogenous (factitious) thyroiditis as well as ectopic thyroid hormone production, such as a hydatidiform mole or struma ovarii, an ovarian tumor composed of some thyroid tissue.

**Thyroid Storm**

Thyroid storm is a rare, life-threatening form of severe thyrotoxicosis. Although it can occur as the result of unrecognized or undertreated thyrotoxicosis, more often it is an acute reaction to thyroid or nonthyroid surgery, trauma, infection, iodine load (contrast media or amiodarone), or parturition in patients with preexisting hyperthyroidism. Other precipitants include acute myocardial infarction, pulmonary embolism, hyperemesis gravidum, toxemia of pregnancy, and diabetic ketoacidosis. Untreated, mortality approaches 100%, but prompt recognition and therapy have lowered mortality from 10% to 30%. Death in thyroid storm is caused by multiorgan dysfunction, congestive heart failure, respiratory failure, arrhythmias, disseminated intravascular coagulation, hypoxic brain insult, or sepsis.

The typical clinical manifestations of thyroid storm include marked pyrexia (104°–106°F [40°–41°C]), extreme tachycardia (often out of proportion to level of fever), and altered mental status (agitation, delirium, or coma). These findings, coupled with the clinical picture of a patient with hyperthyroidism, lid lag, stare, goiter, ophthalmopathy, and tremor should alert the emergency clinician to the diagnosis. Cardiovascular collapse can result in congestive heart failure, hypotension, and cardiac arrhythmias. Hypotension can also result from volume depletion secondary to nausea, vomiting, and diarrhea. Abdominal pain is common; hepatic pain with cholestatic jaundice is less common and carries a poor prognosis. Although no validated diagnostic criteria exist, a scoring system developed by Bahn Chair and colleagues can help distinguish among thyrotoxicosis, impending thyroid storm, and frank thyroid storm (Table 120.1).

**Diagnostic Testing**

The initial diagnosis is based on the clinical picture coupled with confirmatory laboratory values. Measurement of the serum TSH level is the most sensitive test for hyperthyroidism; a normal TSH level excludes hyperthyroidism, and an elevated TSH level is generally diagnostic for hypothyroidism. In thyrotoxicosis, the serum TSH concentration is depressed or undetectable (≤0.01 µIU/mL in third-generation assays). Accuracy of the TSH determination is improved when free T3 is added. Assessment of thyroid function during acute nonthyroidal illness is difficult, especially in critically ill patients. Severe systemic illness depresses TSH production, leading to low levels of TSH, free T3, and free T4. Once referred to as the euthyroid sick syndrome or, more recently, nonthyroidal illness syndrome (NTIS), it appears to be a transient form of central hypothyroidism that occurs in critically ill patients. Although its molecular basis remains unclear, the presence of thyroid dysfunction in critically ill patients predicts adverse outcomes and mortality. At this time, there are no recommendations to treat critically ill patients with NTIS.
Elevation of free T₄ and free T₃ levels in conjunction with TSH suppression is diagnostic of thyrotoxicosis. Because nearly all T₃ and T₄ is bound to TBG, assays measuring total T₃ or T₄ are influenced by changes in TBG; they are therefore unreliable and should not be used. Subclinical hyperthyroidism is likely if TSH is suppressed and the free T₄ level is normal. T₃ toxicosis occurs in about 5% of patients with thyrotoxicosis. These patients have an elevated free T₃ level and a normal free T₄ level. When the reverse pattern is present—normal free T₃ level and elevated free T₄ level, the differential includes thyroiditis, exogenous levothyroxine ingestion, and hyperthyroidism in older adults, often with suppressed T₄ to T₃ conversion due to comorbid illness (Table 120.2).¹

Many thyrotoxic patients have hyperglycemia. This is likely to be the result of increased glycolysis and catecholamine-mediated antagonism of insulin. Mild hypercalcemia can be seen, is related to hormone-mediated bone resorption, and is associated with osteoporosis and increased fracture risk.

The results of liver function tests can be abnormal in thyrotoxic patients. Mild increases in serum aspartate transaminase, alanine transaminase, lactate dehydrogenase, bilirubin, and alkaline phosphatase levels may be seen. Elevations in the serum bilirubin level do not typically result in clinical jaundice. Other frequent laboratory abnormalities include leukocytosis, mild anemia, and low serum cholesterol levels.

In thyroiditis, the diagnostic evaluation is more difficult. An exquisitely tender gland and erythrocyte sedimentation rate (ESR) above 100 mm/hr make the diagnosis of subacute thyroiditis likely. The other forms of thyroiditis lack these findings. Doppler ultrasound examination of the thyroid may be helpful in differentiating among the various causes of thyrotoxicosis. High blood flow in the superior thyroid artery and increased overall tissue blood flow on ultrasound favor Graves’ disease as a cause and make thyroiditis less likely.¹² If factitious thyrotoxicosis is suspected, low thyroglobulin levels may confirm the diagnosis because these levels are elevated in all other forms of thyrotoxicosis. Furthermore, radioactive iodine uptake is depressed in thyroiditis and factitious thyrotoxicosis but increased in hyperthyroidism.

**Differential Diagnosis**

The differential diagnosis for the thyrotoxic patient is broad. An anxious patient may be interpreted to be manic or experiencing a panic attack. The hyperadrenergic state may be confused with that seen in patients with sympathomimetic intoxication, suffering from anticholinergic crisis, or experiencing withdrawal from alcohol or sedative-hypnotics. The hyperpyrexia and altered mental status seen in thyroid storm may mimic other hyperthermic disorders such as heat stroke, neuroleptic malignant syndrome, serotonin syndrome, bacterial meningitis, and sepsis. Older adults with apathetic hyperthyroidism may be mistakenly diagnosed with psychiatric illness.

**Management**

Management of thyrotoxicosis is based on symptom severity. For those with mild symptoms, outpatient referral and management are appropriate. Patients with moderate to severe symptoms are best managed in the emergency department (ED) setting. Treatment is divided into supportive, symptomatic, and thyroid-directed (Box 120.3) therapy. In addition, it is important to identify and treat the precipitating cause of thyroid storm.

**Supportive Treatment**

Supportive therapy for thyroid storm patients should include management of hyperthermia with cooling and acetaminophen. Aspirin should be avoided in thyrotoxic patients because it decreases the protein binding of T₄ and T₃. Agitation is controlled with benzodiazepines. Fluid resuscitation is needed to compensate for insensible and gastrointestinal (GI) losses; dextrose-containing solutions are helpful because glycogen stores are often depleted. Electrolyte replacement is guided by laboratory values.

**Symptomatic Treatment**

Symptomatic treatment consists primarily of beta blockade to diminish the adrenergic response. Traditionally, propranolol has been the beta blocker of choice because it has the added benefit of blocking conversion of T₄ to T₃; its nonselective effects also improve tremor, weakness, hyperpyrexia, restlessness, irritability, and emotional lability. Dosage recommendations vary, but most authors suggest 60 to 80 mg orally every 4 hours.³ The onset of action after oral dosing is about 1 hour.

For rapid beta blockade, propranolol is administered intravenously (IV) as a bolus dose of 0.5 to 1 mg via slow IV push. Propranolol dosing can be repeated, 1 to 2 mg every 15 minutes, as tolerated, until the desired effect is achieved. A short-acting agent such as esmolol may be used when concerns about beta blockade exist. A typical esmolol loading dose is 250 to 500 μg/kg, followed by an infusion of 50 to 100 μg/kg/min. In asthmatics, a β₁-selective drug such as esmolol or metoprolol (50 mg PO every 6–12 hours) may be considered.

If beta blockers are contraindicated, reserpine, 2.5 to 5 mg intramuscularly every 4 hours, is also an option. Patients should be closely monitored for hypotension, regardless of the agent used, because thyrotoxicosis can lower systemic vascular resistance and cause congestive heart failure. Patients who develop clinically significant heart failure should be treated with the usual medications for heart failure, including diuretics and angiotensin-converting enzyme inhibitors. Atrial fibrillation is often refractory to rate control until antithyroid therapy is instituted.

**Thyroid-Directed Treatment**

Thyroid-directed therapy has three goals—reduce thyroid hormone production, prevent thyroid hormone release, and block peripheral conversion of T₄ to T₃. In conjunction with this treatment, an additional goal is the avoidance of therapeutic interventions that may worsen thyrotoxicosis. As such, certain drugs should be avoided in the thyrotoxic patient. Amiodarone

T₃, Triiodothyronine; T₄, thyroxine; TSH, thyroid-stimulating hormone.
and iodinated contrast material both contain iodine and can increase thyroid hormone production. Aspirin can increase free thyroid hormone concentrations through its effect on protein binding. Pseudoephedrine, ketamine, and albuterol increase sympathetic tone and can exacerbate the adrenergic effects of thyrotoxicosis.

Pseudoephedrine, ketamine, and albuterol increase thyroid hormone production. Aspirin can increase free and iodinated contrast material both contain iodine and can increase thyroid hormone production. Aspirin can increase free thyroid hormone concentrations through its effect on protein binding. Pseudoephedrine, ketamine, and albuterol increase sympathetic tone and can exacerbate the adrenergic effects of thyrotoxicosis; when indicated, they should be used cautiously.

Reducing Thyroid Hormone Production. Thionamides inhibit oxidation and organic binding of iodine to thyroglobulin, thereby blocking the synthesis of thyroid hormone. Propylthiouracil (PTU) or methimazole can be used. PTU has the additional effect of impairing the conversion of T₄ to T₃; methimazole has a longer duration of action. PTU is given as an initial loading dose of 500 to 1000 mg orally, followed by 250 mg every 4 hours. The recommended dose for methimazole is 80 to 120 mg daily, divided every 4 to 6 hours. Both PTU and methimazole may be given by nasogastric tube or rectum as needed. Methimazole is available in IV form outside the United States. Although IV administration of methimazole has been attempted, its use is only supported by case reports and should be considered only as a last resort.

Side effects of thionamide therapy range from mild to life-threatening. Mild reactions—urticaria or macular rash, arthralgia, and GI upset—occur in up to 5% of patients receiving methimazole or PTU. Life-threatening side effects are associated with ongoing therapy and occur within the first 90 days of treatment. Agranulocytosis can occur with either drug and should prompt drug discontinuation. PTU-induced hepatotoxicity has earned the drug a black box warning from the US Food and Drug Administration (FDA). Finally, polyarthralitis and vasculitis (drug-induced lupus) can occur; vasculitis is associated with PTU more than with methimazole. Side effects are dose-related for methimazole but not for PTU.

Inhibiting Thyroid Hormone Release. Inorganic iodine blocks the release of stored thyroid hormone. Because an iodine load can increase the synthesis of thyroid hormone, these agents should not be administered until 1 hour after the initiation of PTU or methimazole therapy. Traditionally, oral iodine in the form of potassium iodide (SSKI [saturated solution of potassium iodide], 50 mg iodide/drop), 1 or 2 drops, or Lugol’s solution (8 mg iodide/drop), 5–7 drops PO or PR tid. The recommended dose for methimazole is 80 to 120 mg daily, divided every 4 to 6 hours. The recommended dose for PTU is 500 to 1000 mg orally, followed by 250 mg every 4 hours.

Methimazole, 50–100 µg/kg/min infusion
Strict contraindication to beta blocker—reserpine 2.5–5 mg IM every 4 hr

INHIBITION OF THYROID HORMONE SYNTHESIS
Propylthiouracil, 500–1000 mg loading dose, then 250 mg every 4 hr
or
Methimazole, 60–80 mg/day in divided doses
Preferred route, PO or nasogastric (NG); alternative route: PR (in rectum), enema prepared by pharmacy; same dose for all routes

INHIBITION OF THYROID HORMONE RELEASE
Saturated solution of potassium iodide (SSKI, 50 mg iodide/drop), 1–2 drops PO or PR tid
or
Lugol’s solution (8 mg iodide/drop), 5–7 drops PO or PR tid
or
Sodium iodide, 500 mg IV bid in solution prepared by pharmacy
or
If allergic to iodine, lithium carbonate, 300 mg PO or NG qid

ADMINISTRATION OF CORTICOSTEROIDS
Inhibit T₄ to T₃ conversion; treat relative adrenal insufficiency.
Hydrocortisone, 300 mg IV, followed by 100 mg tid
or
Dexamethasone, 2–4 mg IV qid

DIAGNOSIS AND TREATMENT OF UNDERLYING PRECIPITANT
Consider empirical antibiotics if critical.

SUPPORTIVE MEASURES
Volume resuscitation and replacement of glycogen stores
D₅W/0.9 NS, 125–000 mL/hr, depending on volume status and CHF
Tylenol, with caution
Cooling blanket, fans, ice packs, ice lavage

MISCELLANEOUS
Lorazepam or diazepam as anxiolytic and to decrease central sympathetic outflow
Cholestyramine, an anion exchange resin, interrupts the enterohepatic recirculation of thyroid hormone, 1–4 g PO twice daily for severe or refractory thyrotoxicosis

CHF, Congestive heart failure; D₅W/0.9 NS, 5% dextrose in 0.9% normal saline; IV, intravenously; NG, by nasogastric tube; PO, by mouth; PR, by rectum; T₃, triiodothyronine; T₄, thyroxine.
Thyrotoxicosis and Thyroid Storm Special Situations

CONGESTIVE HEART FAILURE
If rate-related, high-output failure:
- Beta blockade is first-line therapy (dose as in Box 120.3)
- ACEI, digoxin, diuretics as needed
If depressed ejection fraction:
- Avoid beta blocker or one-quarter dose
- ACEI if blood pressure adequate
- Digoxin and furosemide as needed
If pulmonary hypertension:
- Oxygen
- Sildenafil

ATRIAL FIBRILLATION
Beta blocker preferred for rate control (dose as in Box 120.3)
- Calcium channel blockers prone to hypotension; diltiazem, 10-mg test dose. Avoid verapamil.
- Digoxin less effective but may be tried
- Amiodarone should be avoided because of iodine load
- Refractory to conversion to sinus rhythm unless euthyroid first

THYROIDITIS (SUBACUTE)
- NSAIDs for inflammation and pain control
- Prednisone, 40 mg/day, if refractory to NSAIDs
- Beta blockade to control thyrotoxic symptoms
- No role for PTU, methimazole, or iodides

FACTITIOUS THYROTOXICOSIS
- Beta blockade for thyrotoxic symptoms
- Cholestyramine to block absorption of ingested thyroid hormone
- No role for PTU, methimazole, or iodides

ACEI, Angiotensin-converting enzyme inhibitor; NSAIDs, nonsteroidal antiinflammatory drugs; PTU, propylthiouracil.

nor surgery plays a role in the management of thyroid storm or thyrotoxicosis until a sustained euthyroid state has been established because these interventions can precipitate thyroid storm.

First-line treatment of subacute thyroiditis is the use of nonsteroidal antiinflammatory drugs (NSAIDs). Corticosteroids should be used in refractory cases, with an initial dose of 40 mg prednisone daily for 1 to 2 weeks, followed by a taper over at least 2 to 4 weeks. Symptomatic patients should be treated with beta blockers. Management of drug-induced hyperthyroidism involves removal of the offending agent (eg, amiodarone, lithium) and treatment based on the determination of the type of reaction present (eg, iodine-induced thyroiditis, destructive thyroiditis, autoimmune thyroiditis; Box 120.4).

Identification and Treatment of the Precipitating Event
Thyroid storm is often precipitated by a physiologic stressor, usually an infection. Empirical antibiotics are not necessary without an identified source of infection. Other common stressors include myocardial ischemia, pulmonary embolism, and stroke. Management of thyroid storm with PTU, followed by iodine, beta blockers, corticosteroids, fluid resuscitation, rapid cooling, and treatment of the precipitating illness, can resolve fever, tachycardia, and altered mental status within 24 hours. Interruption in therapy should be avoided because it can lead to a sudden recrudescence of symptoms and death.

Disposition
Disposition is guided by symptom severity, with intensive care unit (ICU) admission for patients in thyroid storm. Patients with mild thyrotoxicosis (tremor, tachycardia, nervousness) controlled with a first-line medication who are otherwise stable can be managed as outpatients. Admission to the hospital may be appropriate for patients who require more than beta blockers for symptom control or whose symptoms persist despite therapy. Patients with rapid atrial fibrillation should be admitted to a monitored setting. Patients managed as outpatients can be sent to a primary care physician or referred to an endocrinologist.

HYPOTHYROIDISM

Principles

Background
Hypothyroidism is a condition in which the thyroid gland fails to produce or secrete sufficient circulating thyroid hormone to meet the needs of the peripheral tissues. The condition results from lack of stimulation of the thyroid gland (central or secondary hypothyroidism) or intrinsic gland dysfunction limiting hormone production (primary hypothyroidism). Hypothyroidism is the most common functional disorder of the thyroid gland.

Hypothyroidism is a relatively common disorder of endocrine dysfunction, with an annual incidence affecting approximately 80/100,000 men and 350/100,000 women. Thyroid disorders are the second most common endocrine condition after diabetes mellitus. Higher incidence rates are found in women than in men, which is attributed to the higher prevalence of autoimmune disease found in women in general. In the United States, 1% to 2% of women are affected by hypothyroidism. Subclinical hypothyroidism affects 4% to 10% of the population. There is no specific race or ethnic predilection, but older age groups are at a higher risk for the development of hypothyroidism. The incidence of overt and subclinical hypothyroidism in pregnancy is estimated at up to 0.5% and 3%, respectively.

Pathophysiology
Intrinsic gland failure accounts for up to 99% of all cases of hypothyroidism. Factors that may result in primary hypothyroidism include autoimmune disorders, infiltrative disorders, congenital thyroid dysfuncion, pregnancy, radiotherapy, medications, infection, surgery, inadequate dietary iodine intake, thyroid medication noncompliance, and previous treatment of thyrotoxicosis. Worldwide, iodine deficiency is the most common cause of hypothyroidism; however, in iodine-replete regions, the primary cause is autoimmune. Hypothyroidism may also be associated with other autoimmune diseases, such as diabetes mellitus, pernicious anemia, Addison’s disease, and hyperparathyroidism.

Hashimoto’s thyroiditis, or chronic autoimmune lymphocytic thyroiditis, first described in 1912 by Hakaru Hashimoto, is one of the most common organ-specific autoimmune diseases and the most common cause of primary hypothyroidism. It is characterized by infiltration of the thyroid gland by lymphocytic inflammatory cells, which is then often followed by hypothyroidism as a result of destruction and eventual fibrous replacement of the gland’s follicular tissue.

Neonatal hypothyroidism results from decreased T4 production in the newborn and is the most preventable cause of intellectual disability. Most infants with congenital hypothyroidism have thyroid dysgenesis, which includes thyroid agenesis, thyroid hypogenesis, and a defect in thyroid migration leading to ectopic thyroid tissue, usually found at the base of the tongue (lingual
Lithium and amiodarone are well-known causes of hypothyroidism. Lithium, commonly prescribed for the treatment of bipolar disorder, has a side effect profile that includes goiter in up to 40% and hypothyroidism in about 20% of patients. The most relevant clinical action of lithium on the thyroid is the inhibition of T4 and T3 release. Lithium also increases thyroid autoimmunity if it is present before the initiation of lithium treatment. Treatment with exogenous thyroid hormone is effective, and lithium therapy need not be discontinued.

Amiodarone is a class III antiarrhythmic medication that has a chemical structure similar to that of T4 and contains large amounts of iodine. As such, it inhibits the peripheral conversion of T4 to T3, leading to hypothyroidism. In addition, amiodarone is directly cytotoxic to the thyroid, has the intrinsic effect of blocking thyroid hormone entry into cells, and decreases T3 receptor binding. If amiodarone therapy must be continued for arrhythmia control, patients with amiodarone-induced hypothyroidism may be successfully treated with exogenous thyroid hormone replacement. Patients should be screened with a TSH prior to starting amiodarone. Patients receiving some chemotherapeutic agents are also at risk for thyroid dysfunction.

Insufficient dietary iodine intake leads to reduced T4 and T3 production. Although it is uncommon in developed nations, this is still a major concern in areas where the iodine content in the water is low. The compensatory increase in TSH concentration over time results in the proliferation of gland cells and enlargement of the gland, with a resultant goiter.

Thyroid physiology is altered during pregnancy because increased circulating estrogen increases TBG levels by up to 150%, resulting in lower free T4 levels. Human chorionic gonadotropin (hCG) and TSH have identical subunits, which then both stimulate the release of T4 and T3, resulting in a decreased level of TSH at 8 to 14 weeks of gestation. Increased peripheral metabolism of thyroid hormone occurs primarily in the second and third trimesters. Women with preexisting hypothyroidism will generally require increased doses of replacement hormone in pregnancy.

Although congenital hypothyroidism is one of the most common preventable causes of mental retardation, newborn screening programs in the developed world have made this a rare occurrence in the United States. There are conflicting data and opinions about whether there should be universal screening for thyroid function and subsequent treatment in pregnant women without overt symptoms or risk factors for hypothyroidism. Other obstetric complications of hypothyroidism include miscarriage, anemia, abruptio placenta, postpartum hemorrhage, low birth weight, and neonatal respiratory distress.

Central causes of hypothyroidism are rare and result from hypothalamic dysfunction in the secretion of TRH or pituitary dysfunction in the secretion of TSH. Pituitary adenoma is the most common cause of central hypothyroidism. Other causes include pituitary hemorrhage (Sheehan’s syndrome), pituitary infiltrative processes such as amyloidosis and sarcoidosis, brain injury, and space-occupying mass. Sheehan’s syndrome is a result of postpartum pituitary hemorrhage that leads to pituitary ischemia and necrosis. Patients often have lactation failure, amenorrhea, adrenal insufficiency, and central hypothyroidism.

With advancing age, the thyroid gland changes anatomically, with a reduction in gland size and weight, an increase in fibrosis with lymphocytic proliferation, and a change in colloid content. These changes do not, however, correlate with gland function. TSH levels increase with age, but this is not associated with an increase in T4 concentration.

### Clinical Features

#### History and Physical Examination

Signs and symptoms of hypothyroidism range from asymptomatic to overt organ failure, which may lead to death (Box 120.5). Patients with early hypothyroidism often present with vague complaints. As such, emergency clinicians should consider thyroid dysfunction in patients with generalized arthralgias, infertility or menstrual changes, depression, and hypercholesterolemia.

Typical symptoms develop insidiously and include fatigue, weakness, constipation, heavier menstruation, weight gain, cold intolerance, hypertension, and bradycardia. Skin may be dry, coarse, and pale from fluid accumulation and decreased circulation. Paresthesias of the hands mimicking carpal tunnel have been described.

As the disease progresses, symptoms may include altered or decreased taste, hoarseness, edema of the hands and feet, and slow speech. Body and scalp hair is brittle and coarse, with a high rate of at least some degree of alopecia, thickening of the skin, and thinning of the lateral third of the eyebrows. Facial changes include periorbital edema, broadened nose, swollen lips, macroGLOSSIA, and flat facial expression.

Patients with subclinical hypothyroidism may present with varying nonspecific signs and symptoms similar to those of patients with overt hypothyroidism, but less pronounced. Patients with Hashimoto’s thyroiditis present typically with an insidiously developed goiter and hypothyroidism.

The thyroid has a fundamental role in maintaining cardiovascular homeostasis in physiologic and pathologic states; it influences cardiac contractility, heart rate, diastolic function, and systemic vascular resistance. Increased peripheral vascular resistance and low cardiac output have been suggested to be additional links between hypothyroidism and impaired blood pressure regulation and resultant hypertension. Antihypertensive medications are usually ineffective in noneuthyroid individuals.

The accelerated atherosclerosis in hypothyroidism is ascribed to dyslipidemia, diastolic hypertension, and impaired endothelial function. In addition, T3 increases the production and secretion of renin. In patients who are hypothyroid, renin levels are found to be low, which plays an important role in the acceleration of atherogenesis.

Overt hypothyroidism leads to significant neuropsychiatric impairments of mood and cognition. Subclinical hypothyroidism may cause subtle deficits in memory and cognition. Treatment of subclinical hypothyroidism remains controversial.

Pulmonary abnormalities in hypothyroidism are primarily related to hypoventilation and hypercapnia; up to 65% of patients with pulmonary hypertension have concomitant thyroid dysfunction. Although the exact relationship is unknown, pulmonary artery pressures normalize after treatment of thyroid disease.

In pregnancy, hypothyroidism may be manifested typically, but it is often subtle and difficult to distinguish from normal changes in pregnancy. The secretion of hCG is greatest in the first trimester of pregnancy and plateaus in the second; hCG has inherent TSH-like activity and results in elevated T4 and T3 levels and decreased TSH levels. The fetus begins to produce TSH toward the end of the first trimester; before this time, the fetus relies on maternal TSH production. Normal maternal thyroid hormone production is therefore critical to fetal development.

In children, hypothyroidism may affect growth, development, and cognitive capacity. Declining growth velocity noticed during several years might be the first clue to evaluate for thyroid dysfunction.
CHAPTER 120 Thyroid and Adrenal Disorders

Thyroid and Adrenal Disorders

Mortality rates are high, even with optimum therapy. Without treatment, the mortality approaches 100%. Myxedema is associated with a range of severe mental disorders, from depression to severe psychoses, sometimes called myxedema madness.

Diagnostic Testing

Symptoms and Signs of Hypothyroidism

VITAL SIGNS
Systolic blood pressure, normal or low
Diastolic blood pressure, normal or elevated
Slow pulse to sinus bradycardia
Respirations, normal or slow, shallow
Temperature, normal, but prone to hypothermia with stress

HYPOMETABOLIC COMPLAINTS
Cold intolerance
Fatigue
Weight gain, but decreased appetite

CUTANEOUS
Coarse, brittle hair
Alopecia
Dry skin, decreased perspiration
Pallor, cool hands and feet
Coarse, rough skin
Yellow tinge from carotenemia
Thin, brittle nails
Lateral thinning of the eyebrows

NEUROLOGIC
Slow mentation and speech
Impaired concentrating ability and attention span
Lethargy
Decreased short-term memory
Agitation, psychosis
Seizures
Ataxia, dysmetria
Mononeuropathy
   Carpal tunnel syndrome
   Sensorineural hearing loss
Peripheral neuropathy, paresthesias

MUSCULAR
Proximal myopathy
Pseudohypertrophy
Delayed relaxation of reflexes (hung up or pseudomyotonic)

CARDIAC
Decreased exercise capacity
Dyspnea on exertion

Sinus bradycardia
Long QT with increased ventricular arrhythmia
Chest pain, accelerated coronary disease
Diastolic heart failure (delayed ventricular relaxation)
Pericardial effusion (asymptomatic)
Peripheral edema

Periorbital swelling
Broad nose
Swollen lips
Goiter

Myxedema Coma

Myxedema coma is a life-threatening event, most often precipitated by some stressful occurrence in patients with untreated hypothyroidism. Precipitating events include myocardial infarction, infection, sepsis, stroke, pulmonary embolus, prolonged exposure to cold, or exposure to drugs that suppress the central nervous system (Box 120.6). Diagnosis must often be made on the basis of clinical findings (Box 120.7), and hypothermia is often seen. Treatment of myxedema coma requires potentially toxic doses of thyroid hormone and can precipitate thyroid storm. Mortality rates are high, even with optimum therapy. Without treatment, the mortality approaches 100%. Myxedema is associated with a range of severe mental disorders, from depression to severe psychoses, sometimes called myxedema madness.

Diagnostic Testing

Determination of an elevated TSH level is considered to be the most sensitive and single best screening test to confirm the diagnosis of primary hypothyroidism. TSH levels peak in the evening and are at their lowest in the afternoon, but are also affected by physiologic conditions such as physical stress, illness, trauma, and malnutrition. An elevated TSH level with a low T₄ level is indicative of primary hypothyroidism. Central hypothyroidism is associated with a low or normal TSH level, with a low T₄ level. An increased TSH concentration with a normal T₄ level represents subclinical hypothyroidism (Table 120.3).

OBSTETRIC AND GYNECOLOGIC MEDICAL CONDITIONS

SECTION ELEVEN

Metabolism and Endocrinology

Hypothyroidism

The cornerstone for the treatment of myxedema coma is rapid replacement of IV thyroid hormone (Box 120.8). An initial loading dose of 200 to 400 µg IV should be given, using lower doses in patients who are smaller, older, or have a history of coronary artery disease or arrhythmia. Subsequent daily replacement dose is 1.6 µg/kg body weight, decreasing the dose to 75% if given IV. Controversy exists regarding the use of IV T₃ because it has been shown to increase mortality, and data regarding its use is limited. Stress doses of an IV glucocorticoid are recommended due to possible concomitant adrenal insufficiency. Hydrocortisone, 100 mg IV, is the drug of choice because it has mineralocorticoid and glucocorticoid effects.

Myxedema Coma

The cornerstone for the treatment of myxedema coma is rapid replacement of IV thyroid hormone (Box 120.8). An initial loading dose of 200 to 400 µg IV should be given, using lower doses in patients who are smaller, older, or have a history of coronary artery disease or arrhythmia. Subsequent daily replacement dose is 1.6 µg/kg body weight, decreasing the dose to 75% if given IV. Controversy exists regarding the use of IV T₃ because it has been shown to increase mortality, and data regarding its use is limited. Stress doses of an IV glucocorticoid are recommended due to possible concomitant adrenal insufficiency. Hydrocortisone, 100 mg IV, is the drug of choice because it has mineralocorticoid and glucocorticoid effects.

BOX 120.6

Myxedema Coma: Aggravating or Precipitating Factors

Infection, sepsis (especially pneumonia)
Exposure to cold
Cerebrovascular accident
Drug effect
   Altered sensorium—sedative-hypnotics, narcotics, anesthetics, neuroleptics
   Decreased T₄ and T₃ release—aniodorane, lithium, iodides
   Enhanced elimination of T₄ and T₃; phenytoin, rifampin
   Inadequate thyroid hormone replacement: noncompliance; interference with absorption (iron, calcium, cholestyramine)
Myocardial infarction
Gastrointestinal bleeding
Trauma, burns
Congestive heart failure
Hypoxia
Hypercapnia
Hyponatremia
Hyperglycemia
Hypercalcemia
Diabetic ketoacidosis

T₃, Triiodothyronine; T₄, thyroxine.

BOX 120.7

Recognition of Myxedema Coma

Patient profile—older woman in the winter
Known hypothyroidism; thyroidectomy scar
Hypothermia—temperature usually <95.9°F (36°C); <90°F (32°C) is poor prognostic sign; as low as 75°F (24°C) reported; nearly normal in presence of infection
Altered mental status—lethargy and confusion to stupor and coma, agitation, psychosis, and seizures (myxedema madness)
Hypotension—refractory to volume resuscitation and pressors unless thyroid hormone administered
Slow, shallow respirations with hypercapnia and hypoxia; high risk of respiratory failure
Bradyarrhythmia (sinus), long QT and ventricular arrhythmias
Myxedema facies—puffy eyelids and lips, large tongue, broad nose
Evidence of severe chronic hypothyroidism—skin, hair, reflexes, bradykinesia, voice
Acute precipitating illness (eg, pneumonia)
Drug toxicity (eg, sedative, narcotic, neuroleptic)
Hyponatremia

BOX 120.8

Treatment of Myxedema Coma

Protect airway, ventilatory support; monitor for alkalosis.
Fluid resuscitation
- 0.9 NS or D5/0.9 NS if hypoglycemia
- Watch for unmasking of CHF
Thyroid hormone replacement
- T4 200–400 µg IV (give lower doses to patients who are smaller, have coronary artery disease or a history of arrhythmia) loading dose
- Subsequent daily replacement of 1.6 µg/kg body weight PO, give 75% of this dose if given IV
Hydrocortisone—100 mg IV every 8 hrs
Hyponatremia
- Consider fluid restriction.
- Avoid hypotonic fluids; use only 0.9 NS or D5/0.9 NS.
  If <120 mEq/L consider 3% saline, 50- to 100-mL boluses.
Passive rewarming
- Regular blankets; prevent heat loss.
  If heating blankets are considered, pretreat with IV fluids and monitor blood pressure closely.
- Avoid mechanical stimulation.
- Treatment of any precipitating illness, with special attention to infectious causes.

CHF, Congestive heart failure; D5/0.9 NS, 5% dextrose in 0.9% normal saline; IV, Intravenous; PO, by mouth; T3, triiodothyronine; T4, thyroxine.

Hypotension may respond to crystalloid infusion, but vaso-pressors are occasionally required. In patients with initially refractory hypotension, the mere replacement of thyroid hormone may have a beneficial effect on improvement of blood pressure.

Passive rewarming with blankets and removal from the cold are generally sufficient until the administered thyroid hormone takes effect.

Hyponatremia is not uncommon in patients and is associated with increased mortality. As with other causes of hyponatremia, hypertonic saline should be administered for severe cases of altered mental status or seizures and then corrected more slowly to avoid osmotic demyelination syndrome. The metabolism of sedatives, narcotics, and anesthetics may be slowed, prolonging their effects; lower dosages should be considered.

Disposition

Most patients with hypothyroidism may be treated on an outpatient basis. Patients with severe hypothyroidism who require management or patients with myxedema coma require inpatient care, often in an ICU setting.

ADRENAL INSUFFICIENCY

Principles

Background

First described in 1855 by Thomas Addison, Adrenal insufficiency remains a potentially life-threatening disease. The clinical manifestations are the result of primary adrenal failure or secondary adrenal disease from malfunction of the hypothalamic-pituitary-adrenal (HPA) axis in its production of adrenocorticotropic hormone (ACTH). The predominant symptoms are fatigue, generalized weakness, weight loss, and nonspecific GI symptoms, such as nausea, vomiting, and abdominal pain. Acute manifestations of disease may result in severe refractory hypotension.

Secondary adrenal insufficiency is more common than primary adrenal insufficiency. Its most common cause is exogenous corticosteroid administration.

Anatomy and Physiology

The adrenal glands are responsible for the release of the hormone aldosterone, corticosteroids, and catecholamines. They are paired structures that sit in the retroperitoneum, one atop each kidney. The adrenal gland has two distinct structures—the outer adrenal cortex, comprised anatomically of the zona glomerulosa, and the medulla, comprised anatomically of the zona fasciculata and reticularis. The medulla acts in concert with the central nervous system to produce and secrete epinephrine and norepinephrine in response to sympathetic stimulation. It also secretes the mineralocorticoid cortisol from the zona fasciculata and androgens from the zona reticularis. The outer cortex, which includes the zona glomerulosa, secretes the mineralocorticoid aldosterone.

ACTH, produced and secreted by the anterior pituitary, stimulates the adrenal cortex to synthesize and produce cortisol, which regulates carbohydrate, protein, and lipid metabolism, and aldosterone, which regulates fluid and electrolyte balance through sodium and potassium homeostasis. Cortisol is the primary glucocorticoid in humans, accounting for approximately 95% of all glucocorticoid activity.

Pathophysiology

Primary adrenal insufficiency, or Addison’s disease, is the failure of the adrenal gland to produce cortisol, aldosterone, or both, with an intact HPA axis (Fig. 120.3). In developed countries, it is usually a result of autoimmune destruction. Secondary adrenal insufficiency may occur alone, with other autoimmune diseases (eg, polyglandular autoimmune syndrome type 2, polygenic inheritance), or with hypoparathyroidism and mucocutaneous candidiasis (polyglandular autoimmune syndrome type 1). In primary disease, the HPA axis remains intact. Primary adrenal insufficiency is characterized by absent or low cortisol with high levels of circulating ACTH because of reduced negative feedback effects on the anterior pituitary. The increased ACTH concentration results in secretion of other hormones with similar chemical structure. One classic feature exemplifying this relationship is ACTH stimulation of melanocyte-stimulating hormone, which causes melanocytes to form a black pigment and the characteristic skin hyperpigmentation seen in those with primary adrenal insufficiency.

Secondary adrenal insufficiency is a result of impaired stimulation of the adrenals from the disruption of normal secretion of ACTH by the pituitary (see Fig. 120.3). It is characterized by a low plasma cortisol level, with low circulating ACTH levels. Tertiary adrenal insufficiency is caused by hypothalamic disease. There is a decrease in release of corticotropin-releasing hormone, resulting in minimal ACTH and cortisol production. Aldosterone, sex hormone, and catecholamine synthesis are normal; the most common cause is long-term exogenous steroid administration.

Adrenal insufficiency may be further characterized as acute or chronic (Box 120.9). The most common cause of acute adrenal insufficiency is the exogenous administration of glucocorticoids, which results in suppression of the HPA axis. The degree of suppression varies on the basis of the pharmacokinetics, dose, and duration of the steroid administered. Larger doses of agents with longer half-lives and an extended course of therapy will prolong the suppression of the HPA axis. Although the time for HPA axis recovery after exogenous suppression is highly variable, adrenal insufficiency should be anticipated to occur in patients who...

Clinical Features of Adrenal Insufficiency

The clinical manifestations of chronic adrenal insufficiency are nonspecific and include fatigue, weakness, anorexia, nausea, vomiting, intestinal cramps, and dizziness (Box 120.10). Primary and secondary adrenal insufficiency result in hyponatremia from different mechanisms—aldosterone deficiency and sodium wasting in primary adrenal insufficiency and a low cortisol level and free water retention in secondary adrenal insufficiency. Primary adrenal insufficiency characteristically has more pronounced clinical manifestations than secondary adrenal insufficiency. Patients have symptoms related to a deficiency of glucocorticoids, mineralocorticoids, and androgens. Primary adrenal insufficiency more commonly presents with skin hyperpigmentation, particularly in areas exposed to the sun or subject to friction pressure, salt craving, hyperkalemia, and acidosis. These patients may show signs of sodium and volume depletion (eg, orthostatic hypotension and tachycardia). In secondary adrenal insufficiency, patients more often present with pale skin, loss of hair, decreased libido, and impotence. Glucocorticoid deficiency and low ACTH concentrations may result in hypotension and hyponatremia with normal potassium levels.

Adrenal crisis is usually seen in patients with Addison’s disease because of mineralocorticoid deficiency but can also present in patients with secondary or tertiary adrenal insufficiency who undergo severe physiologic stress, such as surgery, trauma, respiratory distress, hypothermia, myocardial infarction, sepsis, hypoglycemia, pain, depression, and exogenous steroid withdrawal (after suppression of the HPA axis). These stressors deplete cortisol stores, and impair the ability to mount a normal stress response.

Etomide, an IV imidazole agent, has recently been debated as a cause of acute adrenal insufficiency. Etomidate is a selective inhibitor of adrenal 11β-hydroxylase, the enzyme that converts deoxycorticosteroid to cortisol. For this reason, continuous infusions are not recommended. Bolus administration for rapid sequence intubation is regarded as safe.

Diagnostic Testing

Although there are many tests available to confirm the diagnosis of adrenal insufficiency, they require a significant amount of time or serial testing. For this reason, if there is suspicion of adrenal crisis, treatment should be initiated immediately, prior to confirmatory tests.

In stable patients, cortisol measurement is the mainstay for an accurate diagnosis; measurement of the cortisol level in the ACTH

BOX 120.9

Causes of Adrenal Insufficiency

**PRIMARY ADRENAL INSUFFICIENCY**

**Chronic**

Autoimmune adrenalitis (Addison’s disease)—isolated or polyglandular deficiency, human immunodeficiency virus (HIV) infection (direct involvement or disseminated cytomegalovirus, Mycobacterium avium-intracellulare, tuberculosis, cryptococcosis, histoplasmosis, blastomycosis, toxoplasmosis, Pneumocystis pneumonia)

Tuberculosis and disseminated infections as seen with HIV

Metastatic cancer (breast, lung)

Infiltrative (sarcoïd, hemochromatosis, amyloid)

Congenital (adrenal hypoplasia, adrenoleukodystrophy, ACTH resistance)

Bilateral adrenalectomy

Drug toxicity (eg, etomidate, ketoconazole, rifampicin)

**Acute**

Adrenal hemorrhage

Meningococcemia and other sepsis

Anticoagulation (heparins and warfarin)

Anticardiolipin antibody syndrome

Trauma

**SECONDARY ADRENAL FAILURE**

**Chronic**

Pituitary tumor (primary or metastatic)

Pituitary surgery or irradiation

Chronic steroid use with functional deficiency

Infiltrative (sarcoïd, eosinophilic granuloma, tuberculosis)

Traumatic brain injury

Postpartum pituitary necrosis (Sheehan’s syndrome)

Empty sella syndrome

**Acute**

Pituitary apoplexy (hemorrhage into a pituitary tumor)

Postpartum pituitary necrosis (Sheehan’s syndrome)

Traumatic brain injury

Relative adrenal insufficiency (sepsis, hepatic failure, severe acute pancreatitis, trauma)

ACTH, Adrenocorticotropic hormone.

and secondary adrenal insufficiency result in hyponatremia from different mechanisms—aldosterone deficiency and sodium wasting in primary adrenal insufficiency and a low cortisol level and free water retention in secondary adrenal insufficiency.

Primary adrenal insufficiency characteristically has more pronounced clinical manifestations than secondary adrenal insufficiency. Patients have symptoms related to a deficiency of glucocorticoids, mineralocorticoids, and androgens. Primary adrenal insufficiency more commonly presents with skin hyperpigmentation, particularly in areas exposed to the sun or subject to friction pressure, salt craving, hyperkalemia, and acidosis. These patients may show signs of sodium and volume depletion (eg, orthostatic hypotension and tachycardia). In secondary adrenal insufficiency, patients more often present with pale skin, loss of hair, decreased libido, and impotence. Glucocorticoid deficiency and low ACTH concentrations may result in hypotension and hyponatremia with normal potassium levels.

Adrenal crisis presents with hypotension and shock that does not respond to fluid resuscitation and pressors. Patients may have many other nonspecific symptoms, as listed above, but shock is the hallmark.

**Diagnostic Testing**

Although there are many tests available to confirm the diagnosis of adrenal insufficiency, they require a significant amount of time or serial testing. For this reason, if there is suspicion of adrenal crisis, treatment should be initiated immediately, prior to confirmatory tests.

In stable patients, cortisol measurement is the mainstay for an accurate diagnosis; measurement of the cortisol level in the ACTH

**CHAPTER 120 Thyroid and Adrenal Disorders**

1569
stimulation test is the standard method. The test is based on the inability of the adrenal gland to secrete appropriate amounts of cortisol after administration of corticotropin. The test cannot differentiate between primary and secondary adrenal insufficiency because the HPA axis is bypassed and therefore will not alter endogenous ACTH. Baseline cortisol concentrations are determined before and 30 and 60 minutes after IV or intramuscular administration of ACTH, 250 µg. Testing may indicate ACTH concentrations of more than 1000 times the normal physiologic peak for adrenal cortex responsiveness. Random basal serum cortisol concentrations are of limited value for assessment of HPA axis reserve but can confirm an intact adrenocortical reserve if basal morning concentrations are above 500 nmol/L. Cortisol levels peak between 6 and 8 AM, which is the appropriate time to draw blood for the determination of a cortisol level. With cortisol concentration measurements between 100 and 500 nmol/L, further dynamic testing is indicated. More than 90% of cortisol is protein-bound, so changes in protein binding can affect total measured serum cortisol concentrations without affecting free cortisol concentrations.

Mild to moderate hyponatremia, with levels typically above 120 mEq/L, is seen in primary adrenal insufficiency. Aldosterone deficiency leads to sodium wasting, and decreased cortisol levels lead to increased antidiuretic hormone, resulting in increased water absorption. Hyperkalemia may be seen in primary adrenal insufficiency secondary to low circulating aldosterone concentrations, but is not seen in secondary causes when aldosterone is not affected.

Differential Diagnosis

Because of the vague and nonspecific symptoms, the differential diagnosis of hypoadrenalism is extensive. The wasting associated with chronic adrenal insufficiency resembles that of anorexia nervosa or an occult carcinoma. The generalized weakness, fatigue, and myalgias can be confused with chronic fatigue syndrome, polymyalgia rheumatica, myopathy, hypothyroidism, or influenza syndromes. Lack of recognition of acute adrenal crisis with refractory hypotension can result in evaluations for sepsis, GI bleeding, myocardial ischemia, and/or anaphylaxis. Abdominal pain in crisis may be clinically indistinguishable from an acute abdomen, especially if precipitated by adrenal hemorrhage. The headache and visual field cuts in pituitary apoplexy may resemble those of a hemorrhagic stroke. Finally, the constellation of symptoms seen in acute adrenal insufficiency—weakness, malaise, fatigue, nausea, dizziness, and arthralgias—is also present in steroid withdrawal syndrome. Because both can occur with the cessation of chronic glucocorticoid administration, a proper history is critical to distinguish between the two disease processes.

Management

Patients with adrenal insufficiency require hormone replacement to correct a lack of circulating glucocorticoid and mineralocorticoid. Treatment of adrenal crisis should begin as soon as possible and prior to diagnostic testing when crisis is suspected. The first-line treatment is hydrocortisone, 100 mg IV, with IV fluids, pressor support and glucose administration, as indicated (Box 120.11). In hemodynamically stable patients without a known diagnosis, dexamethasone (4-mg IV bolus) can be considered; in contrast to hydrocortisone, it does not interfere with serum cortisol assays. In adults, the typical oral dose of hydrocortisone is 30 mg total daily in split doses. To mimic natural diurnal adrenal variation, two-thirds of the daily dose is usually given in the morning and one-third in the late afternoon. Mineralocorticoid should also be replaced in the form of fludrocortisone, 50 to 200 µg/day. In the setting of fever, infection, or intercurrent illness, the dose of hydrocortisone is doubled. In severe illness, it is commonly increased to 75 to 150 mg daily.

Whereas definitive treatment of secondary adrenal insufficiency is directed at replacement of missing hormone (ACTH or CRH) at the level of the hypothalamus or pituitary, simple steroid hormone replacement is administered in the ED setting. Steroid tapering is necessary when gradual downregulation of the HPA axis has been provoked by exogenous glucocorticoids. There is no universally recommended method for steroid tapering.

Disposition

Most patients with mild symptoms of hypoadrenalism may be discharged for outpatient evaluation and treatment. Severely ill patients should have the underlying disease process identified and treated; an ICU setting is indicated due to the high mortality rate.

**BOX 120.11**

**Treatment of Hypoadrenalism**

**MAINTENANCE**

Hydrocortisone, 20 mg AM, 10 mg PM
Fludrocortisone, 50–100 µg/day

**Maintenance During Minor Illness**

Hydrocortisone, 40 mg AM, 20 mg PM
Fludrocortisone, 50–200 µg daily

**Coverage During Procedural Stress**

Hydrocortisone, 100 mg IV (one time only)

**ADRENAL CRISIS OR RELATIVE ADRENAL INSUFFICIENCY OF CRITICAL ILLNESS**

Dexamethasone, 4 mg IV bolus
or
Hydrocortisone, 100 mg IV bolus
0.9 NS, 2–3 L in the first few hours
Switch to D5/NS if hypoglycemia
Treat precipitating illness

D5/NS, 5% dextrose in normal saline; 0.9 NS, 0.9% normal saline.
Hyperthyroidism
- Thyroid hormone exerts effects on nearly every organ system. A high degree of suspicion is needed to diagnose hyperthyroidism.
- The laboratory evaluation of choice is determination of the TSH concentration with free T₄ and T₃ levels. Total T₄ and T₃ levels are of limited value.
- Thyroid storm is a life-threatening thyrotoxic crisis that requires prompt recognition and therapy, as well as identification and treatment of any precipitating cause, such as infection.
- The order of medication administration in thyroid storm is critical. Iodine can precipitate thyroid storm and must be given a minimum of 1 hour after thionamide therapy (PTU or methimazole). As such, the typical order is beta blocker (propranolol), PTU, or methimazole, and then iodine (SSKI, Lugol’s solution).

Hypothyroidism
- Hypothyroidism results from lack of stimulation of the thyroid gland (central or secondary hypothyroidism) or intrinsic gland dysfunction limiting hormone production (primary hypothyroidism).
- Signs and symptoms of hypothyroidism range from asymptomatic to overt organ failure, which can lead to death.
- Determination of an elevated TSH level is the most sensitive and single best screening test to confirm the diagnosis of primary hypothyroidism.
- Replacement with levothyroxine (T₄) remains the treatment of choice and resolves most physical and psychological signs and symptoms in most patients.
- Myxedema coma is a life-threatening event that is most often precipitated by some stressful event in patients with untreated or undertreated hypothyroidism. Treatment with thyroid hormone replacement must be initiated, often solely on clinical findings.

Adrenal Insufficiency
- Clinical manifestations of primary and secondary adrenal insufficiency may be vague and nonspecific and require a high index of suspicion for diagnosis.
- Predominant complaints include fatigue, weakness, dizziness, nausea, vomiting, and other nonspecific GI symptoms.
- Patients with primary adrenal insufficiency characteristically have more pronounced clinical manifestations and skin hyperpigmentation. Measurement of cortisol in the ACTH stimulation test is the standard and most convenient method to assist in confirming the diagnosis.
- Refractory hypotension in the acutely ill patient may be the only clue to adrenal insufficiency and is readily treated with the IV administration of glucocorticoids (dexamethasone, 4 mg, or hydrocortisone, 100 mg).

The references for this chapter can be found online by accessing the accompanying Expert Consult website.

**CHAPTER 120: QUESTIONS & ANSWERS**

120.1. Which of the following is the single best test to assess thyroid function?  
A. Free T3  
B. Free T4  
C. Total T3  
D. Total T4  
E. TSH  

Answer: E. Reliable assays for serum TSH and free T4 have made the laboratory diagnosis of hyperthyroidism straightforward. Measurement of the serum TSH level is the single best test to assess thyroid function. A normal TSH level excludes hyperthyroidism, and an elevated TSH level is generally diagnostic for hypothyroidism.

120.2. What is the most common cause of hyperthyroidism in the United States?  
A. Graves’ disease  
B. Hashimoto thyroiditis  
C. Hot nodule (toxic adenoma)  
D. Multinodular goiter  
E. Subacute thyroiditis  

Answer: A. In the United States, Graves’ disease (diffuse toxic goiter) is the most common form of hyperthyroidism.

120.3. In thyroid storm, which of the following is the proper sequence of drug administration?  
A. All three together (antithyroid drugs, sodium or potassium iodide, steroid) at the same time  
B. Antithyroid drugs, sodium or potassium iodide, steroid  
C. Sodium or potassium iodide, steroid, antithyroid drugs  
D. Steroid, sodium or potassium iodide, antithyroid drugs  

Answer: B. Because an iodine load can increase the synthesis of thyroid hormone, it should not be administered until 1 hour after the initiation of antithyroid drugs (PTU or methimazole therapy).

120.4. Which of the following medications may cause hypothyroidism secondary to the inhibition of the peripheral conversion of T4 to T3?  
A. Amiodarone (Cordarone)  
B. Digoxin (Lanoxin)  
C. Dopamine (Intropin)  
D. Phenytoin (Dilantin)  
E. Propranolol (Inderal)  

Answer: A. Amiodarone is a class III antiarrhythmic medication that has a similar chemical structure to T4 and contains large amounts of iodine. As such, it inhibits the peripheral conversion of T4 to T3, leading to hypothyroidism. In addition, amiodarone is directly cytotoxic to the thyroid, has the intrinsic effect of blocking thyroid hormone entry into cells, and decreases T3 receptor binding. If amiodarone therapy must be continued for arrhythmia control, patients with amiodarone-induced hypothyroidism may be successfully treated with exogenous thyroid hormone replacement.

120.5. Cardiovascular manifestations of subclinical hypothyroidism include which of the following?  
A. Advanced atherosclerotic plaque formation  
B. Cardiac conduction abnormalities  
C. Decreased peripheral vascular resistance  
D. Labile hypertension  
E. Increased ejection fraction  

Answer: A. Hypothyroidism is responsible for multisystem organ pathology. Even mild thyroid failure is a significant risk factor for the development of arterial stiffness from impaired endothelial function and artery intima–media wall thickening.
Arterial stiffness is an important determinant of premature atherosclerosis and changes in arterial wall elasticity.

The accelerated atherosclerosis in hypothyroidism is ascribed to dyslipidemia, diastolic hypertension, and impaired endothelial function. Additionally, T₃ increases production and secretion of renin. In patients who are hypothyroid, renin levels are found to be low, which plays an important role in the acceleration of atherogenesis.

120.6. In a patient with suspected adrenal crisis, what is the treatment of choice for hypotension refractory to isotonic fluid replacement?
   A. Adrenocorticotropic hormone (ACTH)
   B. Continued normal saline (0.9%) fluid boluses
   C. Dobutamine (Dobutrex)
   D. Dopamine (Intropin)
   E. Hydrocortisone (Solu-Cortef)

Answer: E. Acute manifestations of disease may result in severe and possibly refractory hypotension. Refractory hypotension in the acutely ill patient may be the only clue to adrenal insufficiency and is readily treated with IV glucocorticoids (dexamethasone, 4 mg, or hydrocortisone, 100 mg IV).

120.7. Laboratory confirmation of adrenal insufficiency is performed by measuring the level of the following?
   A. Adrenocorticotropic hormone (ACTH)
   B. Aldosterone
   C. Corticotropin-releasing hormone (CRH)
   D. Cortisol
   E. Melanocyte-stimulating hormone

Answer: D. Maintaining a high index of suspicion for adrenal insufficiency is of primary importance. Several tests are available to assist in confirmation. Whether screening for chronic disease or working up an acutely ill patient, cortisol level measurement is the mainstay of making an accurate diagnosis.
Diphtheria is caused by C. diphtheriae, an unencapsulated, non-motile, gram-positive bacillus named for its shape (korynee, for “club”) and its characteristic clinical presentation (diphtheria, for “leather,” describing the leathery pharyngeal membrane).

Infection with C. diphtheriae can occur at various sites of the respiratory tract or the skin. Respiratory diphtheria includes faucial (pharyngeal or tonsillar), nasal, and laryngeal (tracheobronchial) types, named for the primary location of infection. Cutaneous diphtheria can occur as a primary skin infection or as a secondary infection of a preexisting wound.

Pathophysiology

Toxigenic strains of C. diphtheriae bacterium are lysogenized with the B phage and produce an exotoxin that inhibits cellular protein synthesis. The diphtheritic membrane, composed of leukocytes, erythrocytes, fibrin, epithelial cells, and bacteria, results from necrosis caused by local effects of the exotoxin. Initially, the pharynx appears erythematous, but as necrosis occurs, grayish white patches appear and eventually coalesce. The membrane causes surrounding edema and cervical adenitis. The initial grayish white, filmy appearance changes to a thick, grayish black membrane with sharply defined borders. This membrane adheres to the underlying tissue, and bleeding occurs if removal is attempted.

Circulating exotoxin causes the systemic symptoms of diphtheria, most profoundly affecting the nervous system, heart, and kidneys. The degree of local and systemic toxicity depends on the location and extent of membrane formation. Pharyngeal diphtheria has the greatest toxicity and cutaneous diphtheria has the least. The exotoxin disrupts cellular protein synthesis and causes peripheral neuropathy manifested by muscle weakness. About 5% of patients with respiratory infection will have polyneuritis, but 75% of patients with severe disease have some form of neuropathy. The muscles of the palate are usually affected first. Less commonly, other cranial nerves, peripheral nerves, and the spinal cord are affected. Degenerative lesions develop in dorsal root and ventral horn ganglia of the spinal cord and in cranial nerve nuclei. Cortical cells are spared. Proximal muscle groups are affected first. In severe cases, paralysis may develop in the first few days of illness. In general, the paralysis does not last more than 10 days, but may last up to 3 months. Complete recovery over a longer time is the rule.

Signs of myocardial dysfunction usually appear 1 to 2 weeks after the onset of illness, but may arise earlier in severe cases. The exotoxin directly damages myocardial cells. Electrocardiographic changes suggestive of myocarditis occur in up to two-thirds of
patients, but clinical manifestations of myocarditis occur in only 10% to 25% of cases.

**Clinical Features**

**Symptoms and Signs**

The average incubation period of respiratory tract diphtheria is 2 to 4 days (range 1 to 8 days). Signs and symptoms are indistinguishable from those of other upper respiratory tract infections. Low grade fever and sore throat are the most frequent presenting complaints. Weakness, dysphagia, headache, voice changes, and loss of appetite are also common. Cough, shortness of breath, nasal discharge, and neck edema occur in less than 10% of patients. Cervical adenopathy occurs in approximately one-third of patients, and a membrane is observed in more than half of all patients.

In patients with faucial diphtheria, the extent of the membrane parallels clinical toxicity. If the membrane is limited to the tonsils, the disease may be mild; if it covers the entire pharynx, the onset of illness is usually abrupt and the disease severe. Cervical lymphadenopathy and infiltration of neck tissues may be so extensive that the patient has a “bull-neck” appearance. Patients with this form of malignant diphtheria usually have high fever, severe muscle weakness, vomiting, diarrhea, restlessness, and delirium. Death occurs from respiratory tract obstruction or cardiac failure from myocarditis. Nasal diphtheria presents with serous or sanguineous nasal discharge. A membrane may be visible. These patients do not usually have constitutional symptoms. Treatment is important to prevent a persistent carrier state. Laryngeal diphtheria may begin in the larynx or spread downward. Respiratory tract edema with subsequent upper airway obstruction may develop.

Patients with cutaneous diphtheria typically do not develop systemic toxicity. The skin characteristically has an ulcer with a grayish membrane. Wounds from which *C. diphtheriae* is cultured are clinically indistinguishable from other chronic skin conditions.

**Complications**

The most serious complications of diphtheria are airway obstruction, congestive heart failure, cardiac conduction disturbances, and muscle paralysis. Overall mortality is less than 3% but rises to 7% in patients with myocarditis and 26% in patients with the malignant form of the disease with neck swelling. Although invasive disease is rare, endocarditis, mycotic aneurysms, osteomyelitis, and septic arthritis have all been described in immunocompromised hosts.

**Diagnostic Strategies**

When *C. diphtheriae* is suspected, the laboratory should be notified because routine cultures do not identify the organism. Throat or nasopharyngeal swabs should be obtained for respiratory diphtheria, and if present, membranous material should be examined. Samples should be obtained from skin lesions in cutaneous infections. Specimens should be collected before antibiotic therapy is initiated and transported to the laboratory immediately for rapid inoculation onto tellurite selective culture medium. Definitive identification is made by use of a combination of colony morphology, microscopic appearance, and fermentation reactions. *C. diphtheriae* isolates should be tested for toxin production. The Elek test for toxin A is technically demanding and subject to misinterpretation by inexperienced users but is available at the CDC. Polymerase chain reaction (PCR), which is more reliable but not as readily available, can be used to detect the toxin structural gene. Newer methods that rapidly detect the toxin by mass spectrometry are not readily available but may be used in the future. A positive culture for group A beta-hemolytic streptococcus does not exclude diphtheria, because up to 30% of patients with diphtheria test positive for streptococcal coinfection or carrier state.

Leukocytosis, mild thrombocytopenia, and proteinuria are common but neither sensitive nor specific for diphtheria. Changes on electrocardiogram (ECG) are nonspecific and include ST-T wave changes, varying degrees of atrioventricular block, and
Dysrhythmias. An ECG may be normal even in the presence of myocarditis. An echocardiogram may show dilated or hypertrophic cardiomyopathy. Cardiac enzymes may be elevated, and serum troponin levels correlate with the severity of myocarditis.

**Differential Diagnosis**

It may be difficult to differentiate respiratory diphtheria from many other respiratory conditions, especially in the early phase of infection (Box 121.1). In general, the diphtheritic membrane is darker, grayer, more fibrous, and more firmly attached to the underlying tissues than in other conditions that have a membrane-like appearance. Vincent’s angina frequently involves the gingivae, which are unaffected in diphtheria. Acute bacterial epiglottitis generally has a much more rapid onset than diphtheria, and laryngoscopy reveals an erythematous, edematous epiglottis without membrane formation.

Cutaneous diphtheria is difficult to differentiate from other acute and chronic ulcerative skin lesions. *C. diphtheriae* can secondarily infect any of these lesions, especially in high-risk patients such as alcoholic, and unimmunized or underimmunized people.

**Management**

Patients with clinical evidence of diphtheria should be placed in respiratory isolation and treated presumptively for *C. diphtheriae*. The goals of therapy are to protect the airway, limit the effects of already produced toxin, and stop future toxin production by terminating bacterial growth. Although airway obstruction from diphtheria is rare in the United States, the management is identical to that for other forms of airway obstruction. Early intubation should be considered for patients with laryngeal involvement. Patients may be dehydrated from fever and decreased oral intake related to dysphagia or neurologic impairment. Fluid resuscitation should be undertaken cautiously because the toxin’s effect on the myocardium may result in congestive heart failure.

Equine serum DAT should be administered promptly after the clinical diagnosis of respiratory diphtheria is deemed probable (Box 121.2) and before laboratory confirmation. DAT is not licensed by the U.S. Food and Drug Administration (FDA) for use in the United States, and several countries do not currently hold DAT stockpiles. The CDC can distribute DAT to physicians as an investigational new drug. DAT can be obtained by contacting the CDC Emergency Operations Center at 770-488-7100. The size of investigational new drug. DAT can be obtained by contacting the CDC Emergency Operations Center at 770-488-7100. The size

**BOX 121.2**

**Check List for Assessing a Patient With Suspected Diphtheria**

**SUSPECT CASE**

- Pharyngitis, nasopharyngitis, tonsillitis, laryngitis, tracheitis (or any combination of these), absent or low-grade fever
- Grayish adherent pseudo-membrane present
- Membrane bleeds, if manipulated or dislodged

**PROBABLE CASE**

Suspect case above, plus one or more of the following:

- Stridor
- Bull-neck (cervical edema)
- Toxic circulatory collapse
- Acute renal insufficiency
- Submucosal or subcutaneous petechiae
- Myocarditis
- Death
- Recent return (<2 weeks) from travel to area with endemic diphtheria
- Recent contact (<2 weeks) with confirmed diphtheria case or carrier
- Recent contact (<2 weeks) with visitor from area with endemic diphtheria
- Recent contact with dairy or farm animals or domestic pets
- Immunization status: Note up-to-date DTaP/DT/Tdap/Td shot within past 10 years

**LABORATORY CONFIRMED CASE**

- Positive culture of *Corinebacterium diphtheriae* (or *Corinebacterium ulcerans*) and
- Positive Elek test or
- PCR for tox gene (positive for subunit A and B)

Ergs are recommended, and survivors may have permanent conduction abnormalities. No data support the use of steroids.

Cutaneous lesions should be débrided of necrotic tissue and cleansed vigorously. A course of antibiotics is recommended, but the DAT for cutaneous lesions is of questionable value. Some experts recommend 20,000 to 40,000 units of antitoxin, but few data support its use in this setting. 

Carriers of C. diphtheriae should receive oral penicillin G or erythromycin for 7 days or intramuscular (IM) benzathine penicillin (600,000 units for those weighing less than 30 kg and 1,200,000 units for those weighing more than 30 kg). Active immunization should also be provided to unimmunized and partially immunized carriers. After 2 weeks of therapy, cultures should be obtained; if positive, erythromycin therapy should be given for 10 additional days.

Individuals who have been in close contact with infected patients should have cultures taken and be kept under surveillance for 7 days. Previously immunized close contacts should receive a booster of diphtheria toxoid if the last booster was more than 5 years earlier. The vaccine should be diphtheria, tetanus, and acellular pertussis (DTaP) or diphtheria-tetanus (DT or Td) as appropriate for age. Close unimmunized contacts or those whose immunization status is unknown should receive the same antimicrobial therapy as carriers (previously described), have culture specimens taken before and after therapy, and have active immunization initiated. Close contacts who cannot be kept under surveillance should receive benzathine penicillin intramuscularly to ensure compliance and a Td booster (appropriate for age and immunization history). DAT is not recommended for this group because of the risk of horse serum allergy.

A universal primary immunization program with regular boosters every 10 years is the most effective method for controlling diphtheria. Emergency clinicians should routinely administer age-appropriate tetanus and diphtheria toxoids as part of wound management.

Disposition

All patients with possible pharyngeal diphtheria should be isolated, admitted, and monitored for detection of arrhythmias. A cardiologist should be consulted for patients with evidence of myocarditis. The CDC should be contacted for all suspected or proven cases of diphtheria.

PERTUSSIS

Principles

Background

Pertussis is an acute respiratory disease first described in 1578 when an epidemic swept through Paris. Pertussis means “violent cough.” It is also called whooping cough because the severe episodes of coughing are followed by forceful inspiration, which creates a characteristic whooping sound. Bordet and Gengou identified the causative organism in 1900. In the prevaccination era, pertussis was a major cause of mortality among infants and children. A vaccine was developed in the 1940s, but pertussis still remains a significant cause of morbidity and mortality worldwide.

Epidemiology

Pertussis is a highly contagious respiratory illness transmitted by aerosolized droplets. It can occur at any age but is predominantly a pediatric and adolescent illness. Attack rates are greater than 50% in adults exposed more than 12 years after completion of a vaccination series and up to 90% in susceptible individuals with a household exposure. Half of the cases in the United States occur from June through September. The average incubation period is 7 to 10 days (range less than 1 week to 3 weeks). Neither vaccination nor prior infection confers lifelong immunity.

Pertussis is prevalent worldwide. The World Health Organization (WHO) estimates more than 16 million cases in 2008 with 195,000 deaths. In the United States, annual pertussis rates declined sharply after the introduction of the vaccine, reaching a nadir of 1010 cases in 1976. Since then, there has been a steady increase, with 11,647 cases reported in 2003, 25,616 in 2005, and more than 28,000 cases in 2014 (Fig. 121.2A and B). The incidence is highest in infants who have not received the entire vaccine series (see Fig. 121.2C). Waning immunity in the adult population and increased reporting may be contributing factors. A 1991 report found a possible relationship between the vaccine and acute encephalopathy. Although there appears to be no relationship between the vaccine and long-term neurologic complications, the report resulted in a decline in the use of the whole-cell pertussis vaccine. The acellular pertussis vaccine has been approved in the United States since 1991 for persons 15 months to 64 years and since 1997 for infants.

Etiology

Pertussis is caused by organisms of the Bordetella genus, which are small, aerobic, gram-negative coccobacilli. Bordetella pertussis and Bordetella parapertussis are primarily responsible for human disease. The organisms are fastidious and require a medium containing charcoal, blood, or starch, and an optimal temperature of 95° to 98.6°F (35° to 37°C) to grow. Bordetella bronchiseptica, a flagellated, motile organism, causes illness in animals, including kennel cough, and may rarely cause respiratory infection in immunocompromised humans.

Pathophysiology

Bordetella adhere preferentially to ciliated respiratory epithelial cells, but does not invade beyond the submucosa and is almost never recovered in the bloodstream. It elaborates several toxins that act locally and systemically, including pertussis toxin, dermonecrotic toxin, adenylate cyclase toxin, and tracheal cytotoxin. Local tissue damage consists of inflammatory changes in the respiratory mucosa. Secondary pneumonia or otitis media may occur. Systemic effects of pertussis toxin include sensitization to the lethal effects of histamine and increased excretion of insulin. This hyperinsulinemia can cause hypoglycemia, particularly in young infants.

Clinical Features

Symptoms and Signs

Pertussis has three clinical stages: the catarrhal phase, the paroxysmal phase, and the convalescent phase. The catarrhal or prodromal phase begins after an incubation period of approximately 7 to 10 days and lasts approximately 1 to 2 weeks. Infectivity is greatest during the catarrhal phase, when the disease is clinically indistinguishable from other upper respiratory tract infections. Signs and symptoms include rhinorrhea, low-grade fever, malaise, and conjunctival injection. A dry cough usually begins at the end of the catarrhal phase.

The paroxysmal phase begins as fever subsides. Cough increases and lasts 1 to 6 weeks, but it may persist for up to 10 weeks. Paroxysms of staccato coughing occur and average of 15 times per day and are followed by a single, sudden, forceful inhalation that produces the characteristic “whoop.” Only one-third of adults
with pertussis develop this whoop, and it is rare in young infants, who may present with apneic episodes and no other symptoms. Paroxysms may be spontaneous, occur more frequently at night, or be precipitated by noise or cold. During the paroxysm, the patient may exhibit cyanosis, diaphoresis, tongue protrusion, salivation, and lacrimation. Post-tussive vomiting, syncope, and apnea may occur. Infants may be exhausted after a typical paroxysm. Between episodes of coughing, patients do not appear acutely ill.1,12

In the convalescent phase a residual cough may last several weeks to months. Paroxysms of coughing may be triggered by unrelated respiratory infection or by exposure to a respiratory irritant. This recurrence of coughing does not represent recurrence of pertussis infection.

Atypical presentations can occur in young and preterm infants. Fever is usually absent in uncomplicated neonatal pertussis. Tachypnea, apnea, and cyanotic and bradycardic episodes may be the predominant symptoms.13 Older children and adults who have partial protection from vaccination or previous illness may have a long-lasting intractable dry cough that is frequently misdiagnosed as bronchitis. Post-tussive vomiting in adults is highly suggestive of pertussis.9,14

Physical findings are nonspecific. Tachypnea is variably present and may be related to the degree of pulmonary involvement. Low-grade fever, conjunctival injection, and rhinorrhea are common during the catarrhal phase. Fever during other stages of illness suggests secondary infection. Petechiae above the nipple line, subconjunctival hemorrhages, pneumothorax, and epistaxis may occur because of increased intrathoracic pressure during coughing paroxysms.9,12 Chest examination may reveal ronchi; the presence of rales suggests pneumonia.

Complications

Box 121.3 lists the complications of pertussis. Bacterial or viral pneumonia superinfection complicating pertussis is a leading cause of death, especially in infants and young children. Aspiration of gastric contents and respiratory secretions may occur during paroxysm of coughing, whooping, and vomiting. Secondary pulmonary infection may result from decreased respiratory clearance cause by the *Bordetella* organism and its toxins on bronchial and lung mucosa. A fever during the paroxysmal phase should alert the physician to a possible superinfection.9,10,12

Seizures and encephalopathy occur in about 1% of patients but are more common in infants. This may be due to hypoxia, hypoglycemia, cerebral petechia, toxin effect, or secondary infection by neurotropic viruses or bacteria. Central nervous system (CNS) hemorrhages may occur from the increased cerebrovascular pressures during paroxysm of coughing. Sudden increases in intrathoracic and intra-abdominal pressures can result in several other complications.9,12

Bradycardia, hypotension, and cardiac arrest can occur in neonates and young infants with pertussis. Severe pulmonary hypertension has been recognized in this age group and can lead to systemic hypotension, worsening hypoxia, and increased mortality.13 Intensive care monitoring is recommended for these patients, regardless of how well they appear on admission.

### Diagnostic Strategies

Pertussis should be considered in patients with cough lasting longer than 2 weeks with either paroxysms, whoops, or post-tussive emesis, regardless of previous vaccination status.13 Up to 27% of adults in the United States with a prolonged cough have serologic evidence of pertussis.

Ancillary studies are of limited value in the emergency department. During the late catarrhal and early paroxysmal phases, a marked leukocytosis and a characteristic lymphocytosis are often present. A white blood cell (WBC) count of greater than 20,000/mL is not uncommon.13 Adults with pertussis frequently do not have the characteristic leukocytosis and lymphocytosis, and some infants and immunocompromised hosts may not mount this response. The chest radiograph may show peribronchial thickening, atelectasis, or pulmonary consolidation.

Laboratory confirmation is important for epidemiological purposes. Nasopharyngeal aspirate or swab (synthetic, non-cotton) should be obtained for culture and PCR, if both are available; sputum and throat swabs are inadequate because ciliated respiratory epithelial cells are required.12 The *Bordetella* organism is fastidious, and isolation requires a medium impregnated with antibiotics to reduce overgrowth of competing bacteria. Colonies of *B. pertussis* take 3 to 7 days to appear. Pertussis cultures are 30% to 50% sensitive, and this drops to less than 3% 3 weeks after the onset of cough. Direct fluorescent antibody techniques are useful as a rapid screening test for pertussis but are variably specific and should not be relied upon as laboratory confirmation of *B. pertussis*. Adults generally come to medical attention late in the disease when cultures are rarely positive. PCR is more likely to identify the organism during the first 3 weeks of illness, but it has a high false-positive rate. Serological testing is often performed as well. Most laboratories use enzyme-linked immunosorbent assay, which rises 2 to 3 weeks after infection or primary immunization. Paired serologic tests showing a twofold increase are considered positive; but they are reported as “probable” cases by the CDC unless performed at the CDC or the Massachusetts state laboratory. See Box 121.4 for the case definition.

### Differential Diagnosis

The differential diagnosis includes acute viral upper respiratory tract infection, pneumonia, bronchiolitis, cystic fibrosis, tuberculosis, exacerbation of chronic obstructive pulmonary disease, and foreign body aspiration. The marked leukocytosis may suggest leukemia.

### Management

#### Acute Treatment

Treatment of pertussis is supportive and includes oxygen, frequent suctioning, appropriate hydration, parenteral nutrition as needed, and avoidance of respiratory irritants. Patients with suggested pertussis and associated pneumonia, hypoxia, CNS complications, or those experiencing severe paroxysms should be hospitalized. Children younger than 1 year old should also be admitted, because they are not yet fully immunized and have the greatest risk for
morbidity and mortality. Neonates with pertussis should be admitted to a neonatal intensive care unit (NICU) because apnea and significant cardiac complications can occur without warning. 8,10

Antibiotic treatment does not significantly reduce the severity or duration of illness at any phase. The goal of antibiotic therapy is to decrease infectivity and carriage. 9 The CDC recommends erythromycin estolate ester 40 to 50 mg/kg/day (maximum of 2 g/day) in four divided doses for 14 days. A 7-day course of erythromycin estolate ester at 1 g/day is just as effective at eradicating B. pertussis with better compliance. Azithromycin 10 mg/kg/day for 5 days is recommended in infants younger than 1 year old because of an association between oral erythromycin and hypertrophic pyloric stenosis. Alternative treatments include azithromycin (10 mg/kg on day 1, followed by 5 mg/kg on days 2 to 5) or clarithromycin (15 mg/kg/day; maximum of 1 g/day in two divided doses). Trimethoprim-sulfamethoxazole (8 mg/kg/day of trimethoprim) is an alternative for macrolide-allergic patients, but efficacy is unproven. Patients should be considered infectious for 3 weeks after the onset of the paroxysmal phase or until at least 5 days after antibiotics are started. 9 Strict droplet isolation is recommended during this period.

Corticosteroids, especially in young critically ill infants, may reduce the severity and course of illness, but effectiveness is not established. Beta-2-adrenergic agonists do not reduce the frequency or severity of paroxysmal coughing episodes but may be helpful in patients with reactive airway disease. Trials with pertussis immune globulin are limited and to date show no proven benefit. Standard cough suppressants and antihistamines are ineffective. 15

Postexposure prophylaxis with an appropriate macrolide is recommended for those at high risk for developing severe pertussis, including household contacts of a pertussis case, infants and women in their third trimester of pregnancy, persons with preexisting health conditions that may be exacerbated by a pertussis infection, and contacts who themselves have close contact with any of the above listed people. This includes but is not limited to those who work in NICUs, childcare settings, and maternity wards. Women in their third trimester of pregnancy may be a source of pertussis to their newborn infant. 16

Vaccination

Whole-cell and acellular pertussis vaccines are distributed in combination with diphtheria and tetanus toxoids as DPT and DTaP, respectively. The whole-cell vaccine is 70% to 90% effective at preventing serious pertussis infection. Most recipients have fever, irritability, behavioral changes, and local discomfort at the site of inoculation. Moderately severe reactions are uncommon but include temperature above 104°F (40°C), persistent, high-pitched crying, and seizures. Severe neurologic complications (prolonged seizures and encephalopathy) occur rarely but led to decreased use of the whole-cell form of the vaccine and the development of DTaP. 17 The acellular pertussis vaccines contain inactivated pertussis toxin and one or more other bacterial components; they are less effective than the whole-cell vaccine but have fewer reported adverse reactions. 18,19 DTaP has replaced DPT for childhood immunizations in the United States and is approved for children ages 6 weeks to 6 years old. 20,21 There are three pediatric acellular pertussis vaccines available in the United States. None contains thimerosal as a preservative. Infanrix and Daptacel contain 2-phenoxethanol as a preservative, and Tripea is preservative free.

Pertussis immunity wanes 5 to 10 years after immunization and 15 years after natural infection, causing an increasing incidence of the disease in people older than 15 years old. Tetanus, diphtheria, activated pertussis (Tdap) (with reduced diphtheria toxoid and acellular pertussis) is indicated as a booster vaccine in persons 11 to 18 years old. It is safe and effective in adults, including pregnant women and those over 65 years of age. Persons older than 65 years old who have never received Tdap and anticipate close contact with infants younger than 12 months old should receive a single dose of Tdap, regardless of interval since last Td vaccination. 22,23 A live attenuated nasal vaccine has recently completed phase one trials in humans. 15

TETANUS

Principles

Background

Tetanus is a toxin-mediated disease characterized by severe uncontrolled skeletal muscle spasms. Respiratory muscle involvement leads to hypoventilation, hypoxia, and death. Dramatic descriptions of this disease date to ancient Egypt, when physicians recognized a frequent relationship between tissue injury and subsequent tetanus. 23 Prophylactic injection of tetanus antitoxin provided passive immunity to wounded soldiers during World War I. In 1924, an effective vaccine was developed, and large-scale testing during World War II indicated that the tetanus toxoid confers a high degree of protection against disease. 24

Epidemiology

Despite the availability of an effective vaccine, tetanus remains endemic worldwide. It is more common in warm, damp climates and relatively rare in cold regions. The global annual incidence of reported cases of tetanus has declined with the introduction of vaccination programs (Fig. 121.3A). The WHO reported 14,860 reported cases of tetanus in 2011 but estimates that thousands of unreported cases occur annually resulting is approximately 58,000 neonatal deaths. Most of these cases occur in Africa and Southeast Asia due to low immunization rates and poor hygiene. 23,25
The most common portals of entry are puncture wounds, lacerations, and abrasions. Tetanus has also been reported in association with chronic skin ulcers, abscesses, otitis media, foreign bodies, corneal abrasions, childbirth, and dental procedures. Postoperative tetanus has been reported in patients who have undergone intestinal operations and abortions. In these cases, the source of bacteria is probably endogenous because up to 10% of humans harbor *Clostridium tetani* in the colon.

Inadequate primary immunization and waning immunity continue to be the primary risk factors for tetanus in the United States. As tetanus vaccination of children has improved, older people have accounted for an increasing percentage of reported cases.

Since the introduction of vaccination programs in the United States, the incidence of tetanus has steadily declined from 4 cases per million population in the 1940s to fewer than 0.01 case per million population in 2010 (see Fig. 121.3B).26 The highest incidence occurs in people older than 65 years old (0.23 case per million population), and the incidence in Hispanic Americans is almost twice that in non-Hispanics. Half of cases occur in injection drug users. The overall case fatality rate is 18% but approaches 50% in patients older than 70 years old (Fig. 121.4). Cases have been reported in fully vaccinated patients, but no deaths occurred.26

Tetanus classically occurs as a result of a deep penetrating wound. A history of injury is present in more than 70% of patients, but the injury may be trivial. The remainder may have another identifiable condition or no apparent source.23 The most common portals of entry are puncture wounds, lacerations, and abrasions. Tetanus has also been reported in association with chronic skin ulcers, abscesses, otitis media, foreign bodies, corneal abrasions, childbirth, and dental procedures. Postoperative tetanus has been reported in patients who have undergone intestinal operations and abortions. In these cases, the source of bacteria is probably endogenous because up to 10% of humans harbor *Clostridium tetani* in the colon.

Inadequate primary immunization and waning immunity continue to be the primary risk factors for tetanus in the United States. As tetanus vaccination of children has improved, older people have accounted for an increasing percentage of reported cases.
Etiology

_C. tetani_ is a spore-forming, motile, rod-shaped, obligate anaerobic bacillus. It stains gram-positive in fresh culture but has a variable staining pattern in culture and tissue samples. _C. tetani_ is ubiquitous in soil and dust and is also found in the feces of animals and humans. Spores are resistant to heating and chemical disinfectants and can survive in soil for months to years. When introduced into a wound, spores may not germinate for weeks because of unfavorable tissue conditions. When injury favors anaerobic growth, the spores germinate into mature bacilli, which form a single spherical terminal endospore to produce a characteristic drumstick appearance. Only these mature bacilli produce the tetanus toxin that causes clinical disease.23

Pathophysiology

_C. tetani_ is a noninvasive organism. The development of clinical disease requires a portal of entry and tissue conditions that promote germination and growth in a susceptible host. Tetanus-prone wounds have damaged or devitalized tissue, foreign bodies, or other bacteria. Under these conditions, _C. tetani_ produces the neurotoxin that causes clinical illness. Germination and replication of _C. tetani_ can occur without clinical signs of wound infection.

_C. tetani_ produces the neurotoxin tetanospsamin at the site of tissue injury. Tetanospsamin binds the motor nerve ending and moves by retrograde axonal transport and trans-synaptic spread to the CNS. It binds preferentially to inhibitory (GABAergic and glycnergic) neurons and blocks the presynaptic release of these neurotransmitters. Interneurons afferent to alpha motor neurons are affected first. Without inhibitory control, the motor neurons undergo sustained excitatory discharge, resulting in the muscle spasm characteristic of tetanus.23

Tetanospsamin may also affect preganglionic sympathetic neurons and parasympathetic centers, resulting in autonomic nervous system dysfunction. The clinical manifestations include dysrhythmias and wide fluctuations in blood pressure and heart rate. The binding of tetanospsamin at the synapse is irreversible; recovery occurs only when a new axonal terminal is produced.23

Clinical Features

Symptoms and Signs

The incubation period for tetanus ranges from 1 day to several months. A shorter incubation period portends a worse prognosis.23 The duration of the incubation period is not useful in making the diagnosis of tetanus because many patients have no history of an antecedent wound. Four types of clinical tetanus have been described.

**Generalized Tetanus.** Generalized tetanus, the most common form of the disease, results in spasms of agonist and antagonist muscle groups throughout the body. The classic initial presenting symptom is trismus or “lockjaw,” caused by masseter muscle spasm, and is present in 50% to 75% of patients. As the other facial muscles become involved, a characteristic sardonic smile (risus sardonicus) appears. Other early symptoms include irritability, weakness, myalgias, muscle cramps, dysphagia, hydrophobia, and drooling. As the disease progresses, generalized uncontrollable muscle spasms occur spontaneously or as a result of minor stimuli, such as touch or noise. Spasms can cause vertebral and long bone fractures and tendon rupture. Opisthotonos is prolonged tonic contraction that resembles decorticate posturing. Spasms of laryngeal and respiratory muscles can cause ventilatory failure and death. Autonomic dysfunction is the major cause of death in patients who survive the acute phase and is manifested by tachycardia, hypertension, hyperpyrexia, cardiac dysrhythmias, and diaphoresis. The illness progresses over 2 weeks. If the patient survives, recovery is complete after 4 weeks or more. Throughout the course of this illness, patients remain completely lucid unless they are chemically sedated.23

**Localized Tetanus.** Localized tetanus is a form of the disease characterized by persistent muscle spasms close to the site of injury. Symptoms may be mild or severe, but mortality is lower than with generalized tetanus. Local tetanus may progress to generalized disease. This form of illness may reflect partial immunity to tetanospsamin and may be present for weeks to months before resolution.23

**Cephalic Tetanus.** Cephalic tetanus, a rare variant of localized tetanus, results in cranial nerve palsies and muscle spasms. The palsies precede the spasm in many cases, resulting in misdiagnosis. The most commonly involved cranial nerve is the facial nerve (VII), mimicking Bell’s palsy. Most cases occur after facial trauma or otitis media. Patients have trismus and palsies of cranial nerve III, IV, VII, IX, X, or XII ipsilateral to the site of local infection. The clinical course is variable. In one-third of cases, resolution of symptoms is complete. The remainder progress to generalized tetanus with an overall mortality rate of 15% to 30%.18,23

---

**Fig. 121.4.** Incidence of and mortality from tetanus by age group in the United States, 2000-2009. (Centers for Disease Control and Prevention: Manual for the surveillance of vaccine-preventable diseases. Available at: www.cdc.gov/vaccines/pubs/surv-manual/chpt16-tetanus.html.)
Neonatal Tetanus. Neonatal tetanus is generalized tetanus of the newborn and occurs almost exclusively in developing countries where maternal immunization is inadequate and contaminated material is used to cut and dress umbilical cords. Symptoms begin during the first week of life and include irritability and poor feeding. Mortality approaches 100% because of the high toxin load for body weight and inadequate medical support. Even with limited resources, mortality can be reduced to less than 50% with basic medication and experienced medical personnel.

Complications

Acute respiratory failure results from respiratory muscle spasms or laryngospasms and airway obstruction. If the patient survives the acute onset of illness and has adequate ventilatory support, autonomic dysfunction becomes the leading cause of death. Autonomic instability occurs several days after the onset of generalized spasms. Disinhibition of the sympathetic nervous system predominates and causes dysrhythmias, hypertension, myocarditis, and pulmonary edema. Dysrhythmias and myocardial infarction are the most common fatal events during this phase.

Forceful tetanic muscle spasms can cause vertebral subluxations and fractures, long bone fractures, and shoulder and temporomandibular joint dislocations. Rhabdomyolysis occasionally occurs and can cause acute renal failure. Renal failure may also result from dehydration and sympathetic nervous system hyperactivity.

Secondary infection may occur in the initial inoculating wound or as a complication arising from invasive treatment modalities, such as mechanical ventilation. Hyperthermia may also result from muscle spasms and sympathetic hyperactivity. Prolonged immobility can lead to deep venous thrombosis and pulmonary embolism. Gastrointestinal complications include peptic ulcers, ileus, intestinal perforation, and constipation. The syndrome of inappropriate secretion of antidiuretic hormone occurs in a small number of patients. Hemolysis has also been reported.

Mortality is a function of the previous immunization status, incubation period, severity and rapidity of onset of illness, comorbid disease, age, and sophistication of medical treatment available. With appropriate intensive care treatment, elders may fare as well as their middle-aged counterparts. Long-term physical complications in survivors are rare. The most common persistent problem is psychological trauma related to the disease and its treatment.

Diagnostic Strategies

The diagnosis of tetanus should be made on clinical grounds alone. Wound cultures are of little value and are positive in only one-third of cases. A positive test result, the patient gags and expels the tongue blade. With a negative test result, the patient has reflex masseter muscle spasm and bites the spatula. This test is 94% sensitive and 100% specific for tetanus.

Differential Diagnosis

Strychnine poisoning is the only clinical condition that truly mimics generalized tetanus. Strychnine, like tetanospasmin, antagonizes glycine release, but unlike tetanospasmin, it has no effect on gamma-aminobutyric acid (GABA) release. Patients have opisthotonos while remaining alert. The annual incidences of tetanus and strychnine poisoning are similar in the United States, and serum and urine tests for strychnine should be performed when tetanus is considered.

In patients who present with diffuse generalized spasm, the diagnosis is unlikely to be missed, but ideally the disease should be considered and diagnosed in the early stages to minimize complications and to decrease mortality. Some conditions with clinical similarities to tetanus are listed in Box 121.5. Trismus is most commonly caused by intraoral infections. These can be excluded with careful history and physical examination. Mandibular dislocation can be ruled out with appropriate radiographs of the mandible and temporomandibular joints. Dystonic reactions can be differentiated from tetanus by medication history and symptoms that are alleviated by benztrapine or diphenhydramine. Patients with encephalitis usually exhibit an altered mental status. Meningitis can be excluded by examination of the cerebrospinal fluid (CSF). Rabies should be considered when there are symptoms of brainstem dysfunction, including dysphagia and respiratory muscle dysfunction. A history of exposure to secretions of an infected animal is the most helpful historical point. In addition, rables does not cause trismus.

Cephalic tetanus is especially difficult to diagnose when the cranial nerve palsy precedes trismus. The differential diagnosis of cephalic tetanus also includes Bell’s palsy, botulism, cranial nerve palsies, and facial cellulitis with facial nerve compression and ophthalmoplegia.

Management

Acute Treatment

The four treatment strategies for patients with tetanus should be undertaken simultaneously: aggressive supportive care, elimination of unbound tetanospasmin, active immunization, and prevention of further toxin production.

Supportive Care. Supportive care begins with controlling muscle spasms. Reflex spasms result from stimulation of the patient caused by any movement or loud noises. Unnecessary
stimulation should be avoided. Benzodiazepines are the mainstay of symptomatic therapy for tetanus. These drugs are GABA agonists and indirectly antagonize many of the effects of tetanospasmin. They have no effect on the inhibition of glycine release by tetanospasmin. Diazepam is the most extensively studied, but lorazepam and midazolam are equally effective. Diazepam has a rapid onset of action, wide safety margin, and can be given orally, rectally, or intravenously. It is inexpensive and available in most parts of the world. Its long cumulative half-life and active metabolites can cause prolonged sedation and respiratory depression. The IV formulations of diazepam and lorazepam contain propylene glycol, which, at high doses, can produce lactic acidosis. Gastrointestinal delivery of these agents is limited by motility problems associated with tetanus. Midazolam has a short half-life and does not contain propylene glycol, but should be given by continuous infusion and is cost-prohibitive in most areas of the world. Propofol infusion is effective but expensive, and patients may not tolerate the lipid vehicle. Neuroleptics, barbiturates, and intrathecal baclofen have no advantage over benzodiazepines. Dantrolene is a direct muscle relaxant without CNS activity. It has been reported as an adjunctive agent for muscle spasms and may decrease the need for mechanical ventilation. Magnesium sulfate infusion has been advocated as both adjuvant and first-line therapy for tetanus, although there are no data to support its use in this setting.

If spasm cannot be controlled with these regimens or signs of airway compromise develop, the patient should receive neuromuscular blockade and mechanical ventilation. Succinylcholine can be used in the initial phase of the disease, but there is a risk of severe hyperkalemia resulting from its use in any neuromuscular disease. This effect does not begin until about 4 days after the onset of disease. Long-acting nondepolarizing agents are preferred. Pancuronium has traditionally been used, but it is an inhibitor of catecholamine reuptake and may worsen autonomic instability. Vecuronium and rocuronium are shorter acting, lack significant cardiovascular side effects, but require continuous infusion. Whichever agent is used, adequate sedation should be provided, and neuromuscular blockade should be withheld at least once a day to assess the patient’s status. All intubated patients should be considered for early tracheostomy to decrease reflex spasms caused by the endotracheal tube.

Autonomic instability requires monitoring and aggressive treatment. Sympathetic hyperactivity can be treated with combined alpha- and beta-adrenergic antagonists, such as labetalol and propranolol. The use of beta-antagonists alone can lead to unopposed alpha-activity, resulting in severe hypertension. If beta-antagonists are necessary, a short-acting agent such as esmolol should be used. Clonidine has variable success at modulation of sympathetic outflow in these cases. Morphine and magnesium sulfate infusions as well as spinal anesthesia and intrathecal baclofen have been shown to improve autonomic dysfunction. Diuretics should be avoided for blood pressure control as volume depletion can worsen autonomic instability. Bradydysrhythmia should be treated with temporary pacing. Atropine and sympathomimetic drugs should be used with caution as the autonomic instability is essentially due to catecholamine excess.

Elimination of Unbound Toxin and Active Immunization. Passive immunization with human tetanus immune globulin (HTIG) and active immunization with Td should be initiated as soon as possible in all patients with suspected tetanus. HTIG neutralizes circulating toxin, as well as toxin at the site of production, and reduces mortality; it does not neutralize toxin already present in the nervous system, nor does it treat any existing symptoms. HTIG should be administered at a site separate from the Td. A dose of 500 units is as effective as higher doses. Adult and pediatric doses are the same. Administration of a portion of the HTIG proximal to the site of inoculation is often recommended but has not been studied. The preparation of HTIG available in the United States is not licensed for intrathecal administration, which is questionable benefit.

Prevention of Further Toxin Production. Toxin production is eliminated by treatment of the C. tetani infection. Wound debridement and antibiotic administration can cause a transient release of tetanospasmin, so these measures should be delayed until after the HTIG is administered. Metronidazole (500 mg orally or IV every 6 hours) is the antibiotic of choice for C. tetani. Table 121.1 lists pediatric doses of metronidazole based on age and weight.

Penicillin has good in vitro and in vivo activity against C. tetani, but it also has GABA antagonistic activity and may potentiate the effects of tetanospasmin. Metronidazole has better penetration than penicillin into devitalized tissue and abscesses and is superior in terms of recovery time and effect on mortality. Macrolides, doxycycline, chloramphenicol, and tetracycline are effective alternatives in metronidazole-allergic patients.

Vaccination
Tetanus toxoid is an inactivated form of tetanospasmin. Vaccination confers protective antibody levels in nearly 100% of people who receive three doses. Immunity wanes between 5 and 10 years after completion of the series. In high-risk patients such as elders, injection drug users, and patients with human immunodeficiency virus (HIV) infection and other causes of immunocompromise, immunity wanes more quickly and response to the vaccine is slower.

Adults with an uncertain history of a complete primary immunization series should receive a primary series of three tetanus toxoid doses, followed by booster doses every 10 years. Age-specific guidelines for tetanus prophylaxis have been developed by the Advisory Committee on Immunization Practices (ACIP) and published by the CDC (Tables 121.2 and 121.3).

Tetanus vaccination should be updated for all patients who present for wound management. Patients with unknown or uncertain immunization status should be considered to have no previous tetanus immunization. Those younger than 7 years old should receive diphtheria-tetanus or DTaP. Patients 7 years old or older should receive Tdap.

HTIG prophylaxis (250 units IM) is recommended for unimmunized and underimmunized patients with high risk wounds.

---

**BOTULISM**

**Principles**

**Background**

Botulism is a rare life-threatening paralytic illness caused by neurotoxins produced by *Clostridium botulinum*. The disease occurs in one of five forms: food-borne botulism, infant botulism, wound botulism, unclassified botulism, and inadvertent botulism. Since the approval of botulinum toxins A and B by the FDA for cosmetic and therapeutic uses in the United States, cases of iatrogenic botulism have been reported.

In 1820, Kerner first noted an association between sausage ingestion and a paralytic illness. The term *botulism* comes from the Latin *botulus*, meaning “sausage,” because of these early descriptions of the disease. Botulism first received attention in the United States during World War I when women were encouraged to preserve fruits and vegetables. The recommended heating methods for home canning did not destroy the spores, and epidemics of botulism occurred. Wound botulism was first described in 1943. In 1950 the CDC began surveillance of this form of the disease. Infant botulism, which is now the most common form of the illness, was first described in 1976.

**Epidemiology**

Seven toxins (A through G) are produced by *C. botulinum*. Types A, B, E, and F cause illness in humans, and types C and D cause disease in animals. Type G has been found in soil but has not been linked to human or animal outbreaks. *C. botulinum* spores are found throughout the United States. Type A is more common in the West and type B in the East. Type E is frequently associated with fish products. A total of 160 cases of botulism were reported to the CDC in 2012, which was an increase from 121 cases in 2009; 16% were food-borne botulism, 76% were infant botulism, and 5% were wound botulism. Despite the ubiquitous nature of botulinum spores and the variety of possible routes of toxin entry, the incidence of disease is low.

Typical food-borne botulism results from the ingestion of preformed heat-labile toxin rather than from the ingestion of spores or live bacteria. Food-borne botulism usually results from exposure to home-canned foods that are inadequately preserved and undercooked, but large outbreaks occasionally occur after the ingestion of contaminated food at restaurants or from commercial sources. A variety of preserved foods have been implicated, and...
botulism has also been reported to result from ingestion of improperly prepared and stored fresh foods.

Infant botulism occurs in children younger than 1 year old with a peak incidence between the ages of 6 weeks and 6 months. In contrast to food-borne botulism in adults, infant botulism is caused by the ingestion of spores with in vivo production of toxin. Honey and to a lesser extent corn syrup have been implicated as sources of *C. botulinum* spores in infant botulism. Soil and vacuum cleaner dust have also been implicated, but the source of ingestion remains unknown in most cases. Types A and B botulinum toxins have been responsible for almost all infant cases. There appears to be no relationship between infant botulism and sudden infant death syndrome.

Wound botulism once accounted for approximately one botulism case per year, but the increased use of black tar heroin has resulted in a dramatic increase in cases. Most cases occur in California among injection drug users. Toxin type A is the most frequent causative agent.

Unclassified or adult infectious botulism is a rare illness that is analogous to infant botulism. The *Clostridium* bacterium produces its toxin in vivo. Patients with compromised gastric acidity, disturbances of gastrointestinal motility, or abnormal gastrointestinal bacterial flora may be susceptible to in vivo production of botulinum toxin.

Inadvertent botulism is an iatrogenic form of the disease that occurs in patients who have been treated with injections of botulinum toxin for dystonia and other movement disorders and for cosmetic purposes. Inadvertent generalized weakness as well as unintentional focal weakness may be seen.

The potential exists for botulinum toxin to be used as a biologic weapon. It is highly potent and easy to produce. The Aum Shinrikyo, responsible for the 1995 sarin gas attack on the Tokyo subway, produced and dispersed aerosols of botulinum toxin in Japan on at least three occasions between 1990 and 1995. In 1995, Iraq admitted to the United Nations that it had produced 19,000 L of concentrated botulinum toxin and loaded approximately 10,000 L into warheads. These 19,000 L are not fully accounted for and constitute three times the amount needed to kill the entire human population by inhalation.

**Etiology**

*C. botulinum* is an anaerobic, gram-positive, rod-shaped organism. It forms spores that germinate under certain environmental conditions. It produces a potent exotoxin that is responsible for the disease. Each strain of *C. botulinum* produces a specific toxin type—A through G. Only types A, B, E, and F produce disease in humans. Botulinum toxins are the most potent known biologic compounds. Doses as small as 0.09 to 0.15 μg IV or 0.7 to 0.9 μg inhaled can cause death in a 70-kg human. Heating at 185°F (85°C) for 5 minutes destroys any botulinum toxin, and heating of toxin-contaminated food just before ingestion prevents food-borne botulism. Spores are highly heat resistant and can survive at a temperature of 212°F (100°C) for several hours.

**Pathophysiology**

Food-borne botulism results from ingestion of food that contains preformed toxin. Toxin-contaminated food may have a normal appearance and taste or exhibit signs of spoilage caused by proteolytic enzymes produced by the type A and B strains. Because of the tremendous potency, one taste can expose a person to enough toxin to cause clinical illness. Digestive enzymes do not destroy preformed toxin. Infant and adult infectious botulism results from in vivo bacterial elaboration of toxin in the gastrointestinal tract. Achlorhydria and recent antibiotic use predispose the gastrointestinal tract to colonization with *C. botulinum*. Wound botulism results from in vivo bacterial elaboration of toxin in a wound. Inadvertent or iatrogenic botulism results from injection of preformed toxin for medical purposes. Primate studies indicate that aerosolized botulinum toxin can also be absorbed systemically through the respiratory tract.

The botulinum neurotoxin is similar in structure and function to the tetanuspsamin toxin produced by *C. tetani*, but the clinical effects differ dramatically. Tetanospsamin targets inhibitory interneurons in the CNS, causing generalized muscle spasm, whereas botulinum toxin targets peripheral neuromuscular junctions and autonomic synapses, causing flaccid paralysis. When botulinum toxin is absorbed, it circulates until it reaches the neurons. The toxin binds to the presynaptic nerve membrane, becomes internalized, and inhibits the release of acetylcholine predominantly at the cholinergic synapses of the cranial nerves, autonomic nerves, and neuromuscular junction. Clinically, this is manifested by cranial nerve palsies, parasympathetic blockade, and descending flaccid paralysis. Once affected with type A toxin, the nerve is permanently damaged, and recovery requires axonal regeneration and the formation of new synapses, which may take several months. Recovery after type F toxin is substantially faster.

**Clinical Features**

**Symptoms and Signs**

*Food-borne botulism* is the prototype for understanding the clinical signs and symptoms of all forms of botulism. Symptoms begin 6 hours to 8 days after the ingestion of toxin-containing food. A shorter incubation period is associated with a more severe form of illness. Early symptoms include weakness, malaise, lightheadedness, nausea, vomiting, and constipation. These symptoms are generally not severe and occur in fewer than half of the patients.

Neurologic symptoms may begin immediately or be delayed in onset for several days. The cranial nerves are first affected. Patients experience diplopia, blurred vision, dysphonias, dysphagia, dysarthria, and vertigo. Next, a symmetrical descending muscle weakness occurs, involving the upper and lower extremities and the muscles of respiration. Blockade of the cholinergic fibers of the autonomic nervous system leads to a variety of symptoms. Decreased salivation causes a dry mouth, which may be so severe that the patient complains of a painful tongue and sore throat. Ileus and urinary retention may occur.

The patient with botulism is usually alert and afebrile unless secondary infection is present. Postural hypotension may be present. Ocular signs are prominent and include ptosis, extracocular palsies, and markedly dilated and fixed pupils; the absence of ocular abnormalities does not exclude the diagnosis. The oropharynx may be erythematous, with dry mucous membranes. The gag reflex is depressed or absent. Muscle weakness is usually present and varies from mild to severe. Neck muscles are often weak. Upper extremity muscles are affected more than those of the lower extremity, and proximal muscles are weaker than distal muscles. Deep tendon reflexes may be normal, symmetrically decreased, or absent. The sensory examination is normal. The abdomen may be distended with hypoactive or absent bowel sounds. Bladder distention may be apparent on examination. Respirations may be tachypneic and shallow or normal. In advanced illness, signs of respiratory failure may be present.

Atypical presentations of food-borne botulism have been reported, and certain serotypes produce distinct variations in the pattern of symptoms. Type A disease may be more severe and is more commonly associated with bulbar findings and upper extremity weakness. Type A and type B disease may rarely cause a decreased level of consciousness. Type E is associated with a greater incidence of gastrointestinal symptoms.
The presentation of infant botulism is different from that of food-borne botulism. Constipation is a common presenting complaint, followed by several days to weeks of poor feeding, weak cry, loss of head control, and hypotonia. On physical examination, patients have decreased muscle tone and depressed deep tendon reflexes. Cranial nerve involvement causes alterations in facial expression, ptosis, and extraocular palsies. Respiratory failure occurs in 50% of patients. Fever is absent unless secondary infection is present. Wound botulism has notable differences from food-borne botulism. The incubation period is longer, from 4 to 14 days, because the toxin must be produced within the wound after the spores have germinated. If the wound is infected, the patient may be febrile. Gastrointestinal symptoms are notably absent in wound botulism. Recurrent episodes are well described. The clinical presentation of unclassified (adult infectious) botulism is similar to that of food-borne botulism, although the mortality rate is significantly greater. Recovery from botulism is slow, and survivors are hospitalized for several weeks to months.

Complications
Complications from botulism are related to respiratory failure and problems associated with prolonged intensive care management. Aspiration of oral secretions and gastric contents because of loss of protective airway reflexes can occur. In the past 50 years, the overall mortality rate has decreased from 50% to less than 1% with modern intensive care. Mortality rates are higher in wound botulism patients (15% to 17%) and lower in infant botulism patients (<1%). For those who recover, muscle strength and endurance may not return to normal for up to 1 year, and persistent psychological problems are common.

Diagnostic Strategies
Botulism is a clinical diagnosis that should be considered in any patient who presents with the constellation of gastrointestinal, autonomic, and cranial nerve dysfunction. Bilateral cranial nerve involvement and the progression of neurologic findings should increase clinical suspicion. Routine laboratory studies are of no value in the diagnosis. If a lumbar puncture is performed, the CSF in patients with botulism is normal or may show a slight elevation of protein.

The diagnosis is confirmed by detection of botulinum toxin in the patient’s blood; botulinum toxin or C. botulinum in the gastric contents, stool, or wound of the patient; or toxin or organisms in the suspected food source. Local health departments and the CDC should be notified for instruction on the handling of specimens. Ideally the specimens should be obtained before administration of antitoxin, but treatment should not wait for laboratory confirmation. Serial measurements of the patient’s vital capacity are helpful in recognizing deteriorating ventilatory function. Electromyography can detect abnormalities consistent with the diagnosis of botulism and may be useful in differentiating botulism from other paralytic illnesses. The electromyographic signature of botulism is decreased amplitude of the compound muscle action potential in response to a supramaximal stimulus and facilitation of the muscle action potential with repetitive nerve stimulation. Not all motor units are affected, and normal test results do not exclude the diagnosis.

Differential Diagnosis
The differential diagnosis of adult botulism includes a wide variety of illnesses. Commonly, the first presenting case is misdiagnosed because early symptoms suggest pharyngitis or gastroenteritis, both of which can affect several members of a single household. Only after one or more cases progress to classic botulism is the diagnosis usually suggested. Botulism should be differentiated from other illnesses that cause paralysis. In Guillain-Barré syndrome, weakness usually starts distally and ascends, paresthesias may be present, and the CSF protein level may be elevated. Tick paralysis is an ascending paralysis, which is notable for a lack of bulbar involvement and the presence of a tick. In myasthenia gravis, eye signs are also prominent, but pupillary response is preserved, no autonomic symptoms are present, and weakness responds to the administration of edrophonium or ice applied to the affected muscle group. Of note, minimal improvement in weakness after the administration of edrophonium has been reported in botulism. Poliomyelitis causes fever, asymmetrical neurologic signs, and CSF abnormalities. Diphtheria can be distinguished by the prolonged interval between pharyngitis and neurologic symptoms. Eaton-Lambert syndrome does not usually involve bulbar muscles. Cerebrovascular accidents of the brainstem have an acute onset and asymmetrical, neuroanatomically localizing signs and symptoms.

Certain toxins should also be considered in the differential diagnosis of botulism. Anticholinergics (atropine, belladonna, jimson weed) cause pupillary dilation and dry, red mucous membranes but also cause delirium with alterations in mental status. Organophosphate insecticides cause hyperthermia and altered mental status. Dystonic reactions are self-limited and respond to diphenhydramine or benzotropine. Neuromuscular blockade from the administration of aminoglycosides is distinguished by medication history. Heavy metal poisoning produces changes in mental status. Magnesium toxicity may mimic botulism, but the history and serum magnesium levels distinguish these entities. In paralytic shellfish poisoning, paresthesias are prominent, a history of shellfish ingestion is present, and recovery occurs within 24 hours.

Infant botulism has a broader differential diagnosis. Common illnesses that mimic the presentation of infant botulism include sepsis, viral illnesses, dehydration, encephalitis, meningitis, and failure to thrive. Neurologic illnesses such as Guillain-Barré syndrome, myasthenia gravis, and poliomyelitis should also be considered. Hypothyroidism, hypoglycemia, diphtheria, and toxin exposures are all part of the differential diagnosis consideration, as are less common conditions such as inborn errors of metabolism, congenital muscular dystrophy, and cerebral degenerative diseases.

Management
The treatment of botulism consists of supportive care and specific treatment with antitoxin and other medications to block the effects of the toxin. All patients with suspected botulism should be admitted to the hospital and placed in an intensive care unit (ICU) because respiratory failure may develop rapidly. A decrease in vital capacity to less than 30% of predicted or less than 12 mL/kg is an appropriate criterion for intubation. Ileus should be treated with nasogastric suction and urinary retention with an indwelling urinary catheter. Fortunately, the autonomic dysfunction of botulism is much less severe than that of tetanus and rarely requires intervention.

Saline enemas and cathartics have been recommended by some authors to cleanse the gastrointestinal tract of residual toxin. Cathartics should not be given in the presence of ileus. Magnesium-containing cathartics should be avoided because elevated serum magnesium levels can exacerbate muscle weakness. Special care should be taken with use of gastrointestinal clearance in infants with botulism. Because the source of toxin is outside the gastrointestinal tract in wound botulism, bowel decontamination is not indicated.
Equine antitoxin contains antibodies to toxin types A, B, and E. It should be administered as soon as possible after appropriate laboratory specimens have been obtained. It neutralizes circulating toxin but has no effect on bound toxin. Early administration prevents the progression of illness, decreases hospital length of stay, prevents respiratory failure, and shortens the duration of respiratory failure in patients with severe disease. Antitoxin can be obtained from the CDC or state health department. After skin testing for hypersensitivity, one 10-mL vial should be given IV. The serum half-life is 5 to 8 days. For these reasons, and contrary to the information in the package insert, only one vial of antitoxin is required. Repeated doses are unnecessary and increase the risk of hypersensitivity reactions, which occur in approximately 9% of patients.

Infant botulism is treated with human botulism immune globulin (BabyBIG), which is pooled plasma from immunized adults with high titer of antibodies to toxins A and B. BabyBIG shortens hospital length of stay by a mean of 3.1 weeks and mechanical ventilation by a mean of 1.7 weeks. It can be obtained by calling the California Department of Public Health Infant Botulism Treatment and Prevention Program at 510-231-7600 or 510-540-2646. Antibiotics are not currently recommended for food-borne botulism and may increase cell lysis and promote toxin release. Because the source of toxin is in vivo production within an infected wound, debridement and antibiotic administration should be considered only after antitoxin has been administered. Otherwise, the use of antibiotics should be limited to treatment of secondary infections that may develop. Antibiotic treatment of both infant and wound botulism has no proven benefit. If an antibiotic is used for any reason in a botulism patient, all attempts should be made to avoid the aminoglycosides and tetracyclines because they can impair neuron calcium entry and worsen the effects of botulinum toxin.

Guanidine hydrochloride may enhance the release of acetylcholine from terminal nerve fibers and has been recommended as an experimental component of botulism therapy.

Disposition

All patients with possible botulism should be admitted to the hospital and placed in an ICU as respiratory failure may develop rapidly and insidiously. An infectious disease specialist should be consulted for management issues. The CDC should be called for assistance in any case of suggested botulism. The CDC can be reached by calling 404-639-3311 (days) and 404-639-2540 (nights, weekends, and holidays). State and local health departments may also be helpful in investigating and preventing major epidemics. Area emergency departments should be alerted so that subsequent cases can be looked for and diagnosed.

PNEUMOCOCCEMIA

Principles

Background

Streptococcus pneumoniae is a significant cause of morbidity and mortality worldwide. Pneumococcemia is defined as the presence of S. pneumoniae in the blood. The clinical presentation ranges from a mild illness to a fulminating, life-threatening, systemic syndrome. S. pneumoniae also causes myriad localized infections, including otitis media, pneumonia, meningitis, and, less commonly, endocarditis, septic arthritis, and peritonitis. S. pneumoniae was discovered in 1881 by Sternberg in the United States and simultaneously by Pasteur in France. It was called pneumococcus because it was the most common cause of lobar pneumonia. The first pneumococcal vaccine was licensed for use in the United States in 1977, and today there are two forms available: one for infants younger than 2 years old and individuals with impaired host defenses, and one for otherwise healthy individuals older than 2 years old.

Epidemiology

S. pneumoniae remains a substantial cause of serious illness despite the availability of antibiotics and vaccines. Pneumococcal infection appears sporadically in normal individuals and in patients with impaired host defenses. Most cases of pneumococcal infections are community acquired, and the peak incidence is in winter. Invasive pneumococcal disease (IPD) is defined as isolation of S. pneumoniae from a normally sterile site (blood, pleural fluid, CSF). Pneumococcosis occurs in less than 2% of all hospitalized patients with community-acquired pneumonia, but up to 7.3% of those admitted to the ICU. In 11.5% of those with multilobar infiltrates, 15% of those with a temperature 104°F (40°C) or higher or 95°F (35°C) or lower, 20% of those with a systolic blood pressure below 90 mm Hg, and 22% of those with HIV. Other sources include the meninges (8%) and the sinuses or middle ear (4%). Bacteremia is primary in 18% of adults but much higher in children. People at higher risk for pneumococcosis include those with chronic respiratory or cardiovascular disease, chronic alcohol abusers, patients with cirrhosis, diabetes mellitus, or an absent or functionally impaired spleen (post-splenectomy or sickle cell disease), those receiving immunosuppressive therapy, those with chronic renal failure, nephrotic syndrome, organ transplantation, lymphoma, Hodgkin’s disease, multiple myeloma, and acquired immunodeficiency syndrome (AIDS). Pneumococcus is spread from person to person by close contact, and crowded living conditions are associated with epidemics.

The mortality rate from pneumococcosis is 10% to 20% for young adults and much higher for elders, those with underlying disease, and those with localized infections, such as meningitis. The case fatality rate is significantly lower for children.

Etiology

Pneumococcosis is caused by S. pneumoniae, an encapsulated, gram-positive, facultative anaerobic coccus. Antigenic differences in the polysaccharide capsule separate S. pneumoniae into 90 serotypes. In the United States, the seven serotypes present in Prevnar account for most of invasive disease in children younger than 6 years old and 50% of invasive disease in people older than 6 years old. Worldwide, 10 capsular types account for two-thirds of invasive disease.

Pathophysiology

S. pneumoniae enters the blood by one of two routes: (1) It begins as a pulmonary infection and spreads to mediastinal lymph nodes, the thoracic duct, and into the circulation; (2) it colonizes or causes infection in the upper respiratory tract and spreads to the subarachnoid space through the arachnoid villi to the venous sinus and into the blood (with or without meningeal involvement).

S. pneumoniae bacteremia causes a clinical picture that ranges from a minor febrile illness to life-threatening septic shock. Different capsules of S. pneumoniae confer varying levels of resistance to phagocytosis, resulting in a spectrum of virulence among these serotypes. Multiple virulence factors contribute to adherence to tissues, inhibition of phagocytosis, activation of complement, and stimulation of cytokines.

Host defenses rely heavily upon antibody and complement production, and people who have impaired humoral immunity
are more susceptible to IPD. In patients with pneumococcal infections, antibodies specific to the capsule serotype develop within several days of onset of infection. This response occurs approximately 30 days after a patient receives the pneumococcal vaccine. Patients who demonstrate substantial host resistance are able to develop active immunity, and some children can spontaneously clear culture-proven pneumococemia.

**Clinical Features**

**Symptoms and Signs**

The clinical presentation of pneumococemia ranges from mild illness to fulminant disease, progressing to death within several hours. Occult bacteremia begins as a febrile illness in which the only direct indication of pneumococemia is a positive blood culture (often at 24 to 48 hours). Sepsis is the systemic response to infection, manifested by two or more of the following: (1) temperature higher than 100.4°F (38°C) or lower than 96.8°F (36°C); (2) heart rate higher than 90 beats/minute; (3) respiratory rate of more than 20 breaths/minute or partial pressure of carbon dioxide in arterial gas of less than 32 mm Hg; and (4) WBC count higher than 12,000/mm³, lower than 4000/mm³, or more than 10% immature (band) forms. Patients may present with lethargy, signs of poor tissue perfusion, cyanosis, and hyperventilation or hyperventilation. Either occult bacteremia or sepsis can occur in conjunction with a localized infection.

Symptoms may include fever, chills, cough, shortness of breath, headache, and rash. The shaking chills that occur with pneumococemia are believed to be caused by a toxin. The clinical presentation of pneumococemia is similar to that of other common febrile illnesses. Although signs of focal infection, such as pneumonia, may be present, often the only indication of pneumococemia is fever or other signs of bacterial toxicity.

Most adult patients have fever or hypothermia. Cough, rigors, pleuritic pain, and gastrointestinal symptoms occur in about one-third of adult patients. Patients complain of vague, nonspecific constitutional symptoms similar to those of common viral illnesses. Fever (temperature >101.3°F [38.5°C]) occurs in 90% of younger patients but in less than 60% of those older than 65 years old. Patients with signs of sepsis have an increased risk for a fulminant course with rapid deterioration. Physical examination findings vary with the site of primary infection. A focal primary source of infection is more common in adults than in children. Clinicians should evaluate for signs of otitis media, sinusitis, and meningitis. Pneumococcosis is considered primary in 18% of adults and 30% of children, so lack of localized infection as a source does not rule out IPD.

**Complications**

Cardiovascular collapse can occur with fulminant pneumococcal sepsis. Patients who develop severe illness from pneumococmia may have end-organ damage from inadequate perfusion, disseminated intravascular coagulation (DIC), septic emboli, respiratory failure, meningitis, gastrointestinal bleeding, hepatic coma, renal failure, and myocardial infarction.

Pneumococcosis occasionally results in hematogenous seeding, causing peritonitis, arthritis, endocarditis, meningitis, and cellulitis. Adults and children with functional or anatomic asplenia may have fulminant pneumococcosis, called overwhelming postsplenectomy infection (OPSI), characterized by septic shock, adrenal hemorrhage, and DIC. Although the incidence of OPSI is unknown, studies demonstrate that it is substantial and that the risk for it does not decrease over time after splenectomy. Most invasive pneumococcal infections occur in the first 2 years post-splenectomy, and about two-thirds occur between 5 and 20 years. OPSI may arise with symptoms indistinguishable from those of common viral illnesses. The 100-fold increased incidence of pneumococcal bacteremia and meningitis in children with sickle cell disease is probably primarily due to splenic dysfunction, but complement abnormalities may also play a role.

**Diagnostic Strategies**

The only test specific for pneumococcal meningitis is a blood culture that grows S. pneumoniae. Ancillary testing should include a complete blood count with differential, blood and urine cultures, electrolyte values, glucose concentration, serum creatinine level, serum lactate, and blood urea nitrogen level. A chest radiograph may demonstrate pneumonia. The results of sputum Gram’s stain, culture, and sensitivity testing may help direct later inpatient care. Sputum specimens should be collected before antimicrobial therapy is instituted if possible; however, therapy should not be delayed for the sole purpose of obtaining sputum. Antigen testing of urine for pneumococcal polysaccharide is up to 100% sensitive in IPD.

If the patient appears toxic or has signs of respiratory compromise, an arterial blood gas, serum lactate, and coagulation profile should be obtained. If signs of meningitis or alterations in mental status are present, a lumbar puncture should be performed. Gram’s stain of the buffy coat may be positive in cases of overwhelming pneumococcal sepsis. The WBC count is usually elevated. A normal or low WBC count is suggestive of more serious disease, as are hypoxemia and hypercarbia. Increased mortality occurs in patients with serum creatinine levels higher than 2.0 mg/dL, bilirubin levels higher than 1.5 mg/dL, and albumin levels below 2.5 g/dL.

**Differential Diagnosis**

Pneumococcosis in its more benign form should be differentiated from other febrile illnesses, such as viral infections. The combination of clinical findings and culture results enables one to distinguish between bacteremia and sepsis of other origins. The presence of fever and shock, with or without a distinct rash, suggests the possibility of sepsis caused by Haemophilus influenzae, Neisseria meningitidis, and other streptococcus types. The presence of confirmed pneumococcosis does not exclude other diagnoses, such as influenza and lung cancer.

**Management**

**Acute Treatment**

Management of pneumococcosis consists of stabilization of life-threatening conditions, eradication of the infection, and treatment of predisposing or coexisting conditions. All septic patients should be managed with early goal-directed therapy (see Chapter 130).

The decision to initiate antibiotic therapy is often made with limited objective data, which include the clinical findings, age of the patient, underlying conditions, and possible preliminary laboratory studies.

Prompt initiation of antibiotics is essential to reduce the morbidity and mortality of pneumococcal infection, and should begin in the ED. To simplify selection of a treatment strategy, patients can be divided into three groups:

1. Bacteremia or sepsis suggested by clinical findings; organism not identified: Patients in this group are given broad-spectrum antibiotics, based on the most likely organism, patient’s age, immune status, presence of coexisting disorders, and local patterns of antibiotic resistance. The antibiotic regimen is altered after positive identification of the organism and its sensitivities.
2. *S. pneumoniae* growth is reported from blood cultures (usually 1 to 2 days prior). The treatment regimen for occult bacteremia is guided by the patient's age, history, physical examination, general appearance, and ancillary test results. The antibiotic selected on initial visit may be sufficient to treat pneumococcal bacteremia subsequently identified by the laboratory. The patient should be reevaluated promptly. Repeated blood culture should be obtained if the patient has not been taking an antibiotic. For well-appearing children, a 7- to 10-day course of an appropriate oral antibiotic is reasonable. The decision to admit a child is based on the findings at the time of reevaluation.

3. Bacteremia or sepsis is suggested, and *S. pneumoniae* is identified from a site of local infection, such as Gram's stain of sputum: The antibiotic regimen is focused narrowly.

Adult patients with laboratory-proven pneumococccemia may be treated with penicillin G if susceptibility has been documented: 2 to 4 million units IV every 4 hours if local penicillin resistance patterns are still low. Meningitis is treated with 4 million units of penicillin G every 4 hours. In children, the dosage for meningitis is 250,000 units/kg per 24 hours in divided doses every 4 hours IV up to a maximum of 20 million units.

*S. pneumoniae* susceptible to penicillin in the United States continues to decline.50 Unless penicillin susceptibility has been documented, treatment should begin with either ceftriaxone (1 to 2 g IV every 12 to 24 hours; 50 to 100 mg/kg/day in children) or cefepime (1 to 2 g IV every 12 hours; 50 mg/kg every 8 hours in children). When meningitis is present, the higher doses should be given. In areas where ceftriaxone resistance has emerged, vancomycin should be given (1 g IV every 12 hours; 40 mg/kg/day divided every 6 to 8 hours in children) should be considered. An infectious disease consultant may be able to assist with antibiotic.

IM ceftriaxone is commonly administered to children with suggested occult bacteremia treated as outpatients while blood culture results are pending. Ceftriaxone (initial dose of 50 to 100 mg/kg IM or IV, followed by daily dosage of 100 mg/kg in divided doses every 12 hours, up to a maximum of 4 g) and cefotaxime (200 mg/kg/day in divided doses every 6 hours IV, up to a maximum of 12 g) are excellent antibiotics for *N. meningitidis* and *H. influenzae*. Alternative initial treatment of pneumococcemia in penicillin- or cephalosporin-allergic patients includes vancomycin, imipenem, and chloramphenicol. Chloramphenicol has the associated risk of toxicity and interaction with anticonvulsant medications.

Patients with pneumococcemia may not respond to treatment for the first 24 to 48 hours of therapy. This may be attributed to the normal course of the disease, an incorrect diagnosis, the underlying illness, or an antibiotic regimen that does not treat the infection sufficiently.

**Vaccination**

Pneumococcal vaccine is effective in preventing infection; the currently available 23-valent vaccine contains the purified polysaccharide antigens of the serotypes that cause 70% to 88% of pneumococcal infections in the United States. Although it is only 60% to 70% effective at preventing invasive disease, it is safe, inexpensive, and of substantial value for well-defined groups at risk.59,62 The 23-valent pneumococcal vaccine has limited immunogenicity in children younger than 2 years. The heptavalent conjugate vaccine PCV7, licensed in 2000, linked the polysaccharide to proteins, resulting in an improved immunogenic response in children younger than 2 years old.53 This vaccine significantly decreased IPD caused by the included serotypes, but an increase in disease caused but non-vaccine serotypes prompted the development of a 13-valent conjugate vaccine. PCV13 was licensed in the United States in 2010 and has replaced PCV7.59 Recommendations for the use of the PVC13 and 23-valent (PPSV23) vaccines are given in Tables 121.4, 121.5, and 121.6.52,53

Approximately 50% of IPD in children with comorbidities is caused by serotypes not included in either the 13-valent or 23-valent vaccine.64 Other preventive measures for pneumococccemia include passive immunization with immunoglobulins for patients with congenital or acquired immunodeficiency diseases and daily antibiotic prophylaxis for children with functional or anatomic asplenia.55

**Disposition**

Disposition of the patient depends on the patient's age, clinical condition, and presence of coexisting illnesses. Toxically appearing patients of any age should be promptly treated with antibiotics and admitted to the hospital. Patients with underlying or coexisting conditions and those with an unclear course of illness should also be admitted or observed.

Children who are afebrile and appear well at the time of the initial examination are unlikely to have serious sequelae. The decision to treat a febrile child with antibiotics on an outpatient basis should be based on clinical findings, vaccination history, medical history, ability of the parents to follow the discharge instructions, and availability of timely follow-up.

**MENINGOCOCCEMIA**

**Principles**

**Background**

Few clinical situations in emergency medicine produce greater anxiety than meningococcal infection. Virtually all experienced emergency clinicians have had a patient who appeared relatively well on initial presentation, only to be moribund and in critical condition with fulminant infection several hours later. Vieusseux initially described “Epidemic cerebrospinal fever” in 1805, and Weichselbaum identified the causative bacterial agent in 1887. The introduction of sulfonamide therapy in 1937 dramatically improved outcome. Sulfonamide prophylaxis was also effective at eradication of the carrier state and was used to prevent epidemics that occurred in military barracks. In the 1940s, sulfonamide resistance began to emerge. In 1965 an outbreak of resistant meningococcal disease occurred in the United States, which spurred efforts to develop a vaccine. Subsequent worldwide resistance has resulted in continued efforts to develop safe and effective vaccines.56

**Epidemiology**

Humans are the only reservoir for *N. meningitidis*. In 2013, 564 cases of meningococcal disease were reported in the United States. Active Bacterial Core surveillance by the CDC reports an incidence of 0.14 per 100,000 population, a marked decrease since the licensing of the first conjugated meningococcal vaccine in 2005 (Fig. 121.5). Of the more than 13 serogroups, groups A, B, C, Y, and W-135 cause most of the infections. Most cases occur sporadically, with occasional outbreaks, notably on college campuses in dormitories or in other crowded living situations. More than half of the cases in infants are caused by serogroup B, for which there is no effective vaccine. Serogroups C, Y, and W-135 cause 75% of meningococcal disease in patients older than 11 years old.56 Although grouping is important for tracking of the disease, all groups are capable of causing the same spectrum of clinical disease.

All adults 65 years old or older should receive a dose of PPSV23, regardless of previous history of vaccination with pneumococcal vaccine.

Including chronic obstructive pulmonary disease, emphysema, and asthma.

Includes B- (humoral) or T-lymphocyte deficiency, complement deficiencies (particularly C1, C2, C3, and C4 deficiencies), and phagocytic disorders (excluding chronic granulomatous disease).

Diseases requiring treatment with immunosuppressive drugs, including long-term systemic corticosteroids and radiation therapy.

CSF, Cerebrospinal fluid; HIV, human immunodeficiency virus.

Advisory Committee on Immunization Practices (ACIP), United States, 2010.
The incidence of meningococcal disease peaks in the winter. Superimposed on this annual variation are cyclic peaks of disease every 5 to 15 years. Approximately every 10 years, massive outbreaks of serogroup A occur in sub-Saharan Africa (the “meningitis belt”). The last outbreak was in 2013 with over 9000 cases and close to 900 deaths.57 During nonepidemic periods, children younger than 5 years old have the highest incidence of infection. During epidemics, the incidence increases among children aged 5 to 9 years, an observation that may be of value in predicting the beginning of an epidemic. Crowded living conditions increase the risk for spread of meningococcal disease. The incidence of disease and the carrier state are several times higher among military recruits in the first few weeks of service than in the general public. This is also true of college freshmen, particularly those living in dormitories. Other risk factors for development of invasive meningococcal disease include close contact with an infected patient, complement deficiency, properdin deficiency, asplenia, chronic alcohol abuse, active and passive smoking, corticosteroid use, and recent respiratory illness.

The mortality rate of meningococcal meningitis is 40% in the United States. Septicemia without meningitis carries a much higher mortality rate (up to 70%) than meningitis alone (less than 10%).55,56,58

**Etiology**

Meningococcal disease is caused by *N. meningitidis*, a fastidious, aerobic, gram-negative diplococcus. *N. meningitidis* is an encapsulated organism classified into at least 13 serogroups on the basis of the capsular polysaccharides.55

**Pathophysiology**

*N. meningitidis* is an obligate human pathogen. It attaches to nonciliated epithelial cells in the nasopharynx. It may either remain on the epithelial surface, causing an asymptomatic carrier state, or produce mild symptoms of an upper respiratory tract infection. The carriage state acts as an immunizing process. In certain patients, the bacteria enter the bloodstream and cause localized infection, bacteremia, sepsis, or fulminant infection. Multiple host and microorganism characteristics may determine whether clinical disease develops, but the presence of bactericidal antibodies is protective. Complement deficiency plays a role in a host’s inability to fight this infection. The capsule is required for adherence to epithelium, but only unencapsulated meningococci enter epithelial cells; capsular biosynthesis has been shown to stop as the bacteria enter the epithelial cell.55 The release of lipo-oligosaccharide (LOS) and endotoxin by autolysis of the *N. meningitidis* cell is the initial event in the development of meningococcal sepsis. LOS stimulates a massive host mediator response. All of the major pathophysiologic events of meningococcal sepsis are caused by the host’s inflammatory response to the organism causing functional and histologic damage to the microvasculature, resulting in increased vascular permeability, pathologic vasoconstriction and vasodilation, loss of thrombore sistance, DIC, and profound myocardial dysfunction.56

**Clinical Features**

**Symptoms and Signs**

Presentation of meningococcemia ranges from a mild febrile illness to fulminant disease progressing to death within hours. Most patients have fever on presentation. Other complaints include headache, irritability, lethargy, myalgias, emesis, diarrhea, cough, and rhinorrhea. Anywhere from 27% to 77% of patients will present with the classic hemorrhagic skin lesions.55 These patients can rapidly progress to purpura fulminans, with hypotension, adrenal hemorrhage, and multiorgan failure. The following categories detail the five patterns of presentation.

**Occult Bacteremia.** This condition is a febrile illness in which the only direct indication of meningococcemia is a positive blood culture, with results available most often 24 to 48 hours after initial evaluation. In its mildest form, meningococcal bacteremia cannot clinically be distinguished from more benign febrile illnesses. Initial diagnoses in these patients include common childhood infections, such as otitis media, acute viral upper respiratory infections, and gastroenteritis. For some patients the illness resolves after treatment with an oral regimen of antibiotics; others experience spontaneous resolution without antibiotic treatment. *N. meningitidis* accounts for less than 1% of occult bacteremia cases, but these patients are much more likely to develop meningitis (up to 58%) than are those with *S. pneumoniae*.

Despite the total absence of clinical clues to meningococcal infection at initial presentation, some untreated patients subsequently deteriorate rapidly.

**Meningococcal Meningitis.** Patients with meningococcal meningitis present similarly to those with meningitis of other causes, with headache, photophobia, vomiting, fever, and signs of meningeal inflammation. This classic triad of fever, neck stiffness, and altered mental status is present in less than 30% of patients.59 Infants and small children may present with fever, irritability, and vomiting as the only complaints. More than half of patients with meningococcal meningitis have rash on presentation, and 20% present with seizures. Onset of symptoms is less abrupt (usually during 24 hours) and prognosis is better for patients with meningococcal meningitis than for patients with meningococcemia without clinical signs of meningitis.

**Meningococcal Septicemia.** Patients with meningococcal septicemia present with lethargy, poor tissue perfusion, cyanosis, and hypoventilation or hyperventilation. Hemorrhagic skin lesions are present in 28% to 77% of patients, but a macular or maculopapular rash may occur and be mistaken for a variety of viral exanthems. Petechiae generally appear on the extremities and under pressure points, such as the elastic bands of socks and underwear. They may progress to involve almost any body surface, including the mucosa and sclera, but typically spare the palms, soles, and head. Macular lesions may progress to purpura and ecchymoses in fulminant meningococcemia. The purpurae are not a coalescence of petechiae but a distinct entity that more specifically characterizes meningococcemia. *Purpura fulminans,*
the most advanced form of meningococcal septicemia, occurs most often in children and is usually associated with DIC. This condition is characterized by rapidly spreading ecchymoses and gangrene of the extremities. Mucosal and gastrointestinal bleeding as well as oozing from intravenous (IV) sites may occur. Clinical signs of meningitis and CSF pleocytosis may not be present, even when diplococci are isolated from the CSF. This is probably because the systemic progression of the disease is so rapid that it precludes a host meningeal inflammatory response to the organism in the CSF. Shock results from both intravascular volume loss and congestive heart failure, probably related to myocarditis. Renal failure, coma, and bilateral adrenal hemorrhage often occur.5

Fever and a Nonblanching Rash. Up to 30% of patients present without signs of meningitis or septicemia. They are typically admitted for fever and a nonblanching rash and no other specific findings. If they are untreated, meningitis or fulminant septicemia and shock can develop.3,4

Chronic Meningococcemia. This syndrome is characterized by fever, rash, and arthritis in conjunction with a positive blood culture for \( \textit{N. meningitidis} \). Headache and upper respiratory symptoms are often present. This is the rarest form of meningococcal disease, accounting for less than 2% of cases. It may progress to meningitis, endocarditis, or fulminant meningococcemia regardless of treatment.

Complications

Circulatory collapse is a common complication of meningococcemia and the most common cause of death. Many of the inflammatory mediators released during sepsis cause peripheral vasodilation, capillary leak, and myocardial dysfunction. Acidosis, hypoglycemia, hypokalemia, hypocalcemia, hypophosphatemia, and hypoxia also contribute to the myocardial dysfunction, which may become unresponsive to positive inotropic medications. Acute respiratory failure occurs from capillary leak, DIC, and large volume requirements in the setting of decreased cardiac function. Patients frequently require mechanical ventilation. Renal failure is common due to impaired renal perfusion. If meningitis accompanies meningococcemia, focal neurologic deficits and seizures may occur but are less common than with pneumococcal meningitis. Long-term neurological sequelae include hearing loss, visual deficits, neurodevelopmental impairment, cranial nerve palsies, and hemi- and quadripareis. Purpura fulminans may result in skin lesions that necessitate plastic surgery and loss of digits or limbs from gangrene. Purulent or immune complex arthritis and pericarditis with tamponade may also occur. Herpes labialis occurs in 5% to 20% of patients with meningococcal disease.

Poor prognostic indicators include seizures, hypothermia, hyperpyrexia, total peripheral WBC count of less than 500/mm\(^3\), platelet count of less than 100,000/mm\(^3\), metabolic acidosis (pH <7.30), development of purpura fulminans, onset of petechiae within 12 hours of admission, absence of meningitis, presence of shock, low sedimentation rate, and extremes of age. In one study, all patients who developed organ system failure had one or more of the following at the time of initial presentation: circulatory insufficiency (hypotension or shock), peripheral WBC count of less than 10,000 cells/mm\(^3\), or a coagulopathy.5

Diagnostic Strategies

The tentative diagnosis of meningococcemia is based on clinical findings and confirmed by the isolation of \( \textit{N. meningitidis} \) from blood cultures or any other usually sterile site, such as CSF or synovial, pleural, or pericardial fluid. Ideally, blood culture specimens should be obtained before the administration of antibiotics unless this unduly delays the patient’s treatment. Blood cultures are positive in approximately 50% to 80% of cases. A lumbar puncture should be performed only in stable patients without evidence of DIC. The CSF shows either gram-negative diplococci on Gram’s stain or a positive culture in about 46% to 94% of cases. Even patients without clinical signs of meningitis frequently have the organism grown from the CSF. Gram’s stain of petechial scrapings may show gram-negative diplococci in up to two-thirds of cases, and the organism can rarely be seen in the peripheral blood buffy coat. Highly specific antigen tests for CSF are available but have a high false-negative rate. PCR of theuffy coat or CSF is more sensitive and specific than any of the preceding tests and is not affected by prior antibiotic therapy.

Ancillary laboratory tests are of little value in establishing a specific diagnosis of meningococcal sepsis but may be useful in ruling out other disease, determining prognosis, and monitoring complications. The WBC count may be high, low, or normal, but a bactemia is typically present. The symptoms and signs of CNS infection may be nonspecific in the infant and child younger than 2 years old. If meningitis is present, the CSF opening pressure is usually elevated, the protein level is increased, and the glucose concentration is decreased. Pleocytosis is usually present, with a predominance of polymorphonuclear leukocytes. Gram-negative diplococci may be seen on microscopy. Early in the disease or with fulminant disease, the CSF may be free of inflammatory cells. Serologic evidence of DIC is frequently present.6,7 A chest radiograph is useful in evaluation for pneumonia and acute respiratory distress syndrome. An echocardiogram helps assess for myocardial dysfunction and pericardial effusion. Serum lactate may help direct therapy.

Differential Diagnosis

It is difficult to distinguish the clinical signs of meningococcemia from those of bacteremia caused by \( \textit{S. pneumoniae} \), other streptococcal groups, \( \textit{H. influenzae} \), and \( \textit{Neisseria gonorrhoeae} \). A hemorrhagic rash is more commonly associated with meningococcal disease. The differential diagnosis of meningococcemia also includes viral exanthems, Rocky Mountain spotted fever, typhus, typhoid fever, endocarditis, vasculitis syndromes (polyarteritis nodosa and Henoch-Schönlein purpura), toxic shock syndrome (TSS), acute rheumatic fever, dengue fever, drug reactions, idiopathic thrombocytopenic purpura, and thrombotic thrombocytopenic purpura.

Management

Acute Treatment

Morbidity and mortality in meningococcemia are reduced with prompt recognition and immediate antibiotic therapy. Delays of therapy for the completion of diagnostic studies or admission to an inpatient unit should be avoided. To simplify selection of a treatment strategy, patients can be divided into three general groups:

1. Bacteremia or sepsis suggested by clinical findings; no organism identified: Patients should receive broad-spectrum antibiotics based on factors that include the most likely organism, patient’s age and immune status, presence of coexisting disorders, and local patterns of antibiotic resistance. A narrower spectrum agent is selected after positive identification of the organism and its sensitivities.

2. \( \textit{N. meningitidis} \) growth is reported from prior blood cultures: Treatment for occult bacteremia is guided by the patient’s age, history, physical examination, general appearance, and
ancillary test results. The antibiotic selected at the time of the initial visit may be sufficient to treat the meningococcal bacteremia subsequently identified by the laboratory. The decision to hospitalize the patient is based on the findings at the time of reevaluation and the risk of sequelae. Regardless of clinical appearance, most physicians would draw blood for repeated cultures, consider lumbar puncture, and admit the patient to the hospital until results of repeated cultures are obtained.

3. Bacteremia or sepsis is suggested and N. meningitidis is identified. The antibiotic regimen is focused narrowly.

The standard antibiotic regimen for laboratory-proven meningococcal gococcemia is penicillin G (4 million units every 4 hours IV for adults) and penicillin (250,000 to 300,000 units/kg/day in divided doses every 4 hours IV for children, up to a maximum of 20 million units). Penicillin resistance in N. meningitidis remains low in the United States but has been reported in Spain and the United Kingdom.

Although appropriate first-line therapy, penicillin is rarely given as the initial agent in patients with suspected meningococcal sepsis or meningitis. Ceftriaxone (100 mg/kg IV, followed by daily dosage of 100 mg/kg in divided doses every 12 hours, up to a maximum of 4 g) and cefotaxime (100 mg/kg/day IV in divided doses every 6 hours, up to a maximum of 12 g) are appropriate initial antibiotics as well. The cephalosporins are safe and have rapid onset of action and excellent coverage for S. pneumoniae and H. influenzae. Chloramphenicol (100 mg/kg/day divided every 6 hours to a maximum of 4 g/day) should be considered in penicillin- and cephalosporin-allergic patients. IM ceftriaxone is occasionally administered to children with suspected bacteremia who are treated as outpatients while culture results are pending. Several reports have demonstrated the efficacy of ceftriaxone (80 to 100 mg/kg IV) in a single daily dose; however, twice-daily dosing remains the standard recommendation at this time. Ceftriaxone-treated patients have a more rapid sterilization of the CSF and a lower incidence of hearing loss than conventionally treated patients.

Patients with fulminant meningococcal require prompt airway management, IV fluid resuscitation, and vasopressor support. Fluid requirements may be high because of third spacing of fluid; and in the setting of frequent myocardial dysfunction, intensive cardiovascular monitoring is required. Electrolyte and acid-base abnormalities should be corrected. If the patient is oliguric or anuric, hemodialysis may be necessary to correct these abnormalities. Fresh frozen plasma should be considered for patients with bleeding complications.

The role of steroids for the treatment of meningococcal without meningitis remains controversial. Although corticosteroids were once widely recommended for the treatment of meningococcal meningitis, the organism is typically not identified when steroids are administered. Dexamethasone (0.4 to 0.6 mg/kg/day every 6 hours for 4 days) should be given to patients with bacterial meningitis. The first dose should be given before the first dose of antibiotics if possible.

Plasmapheresis, blood exchange, and extracorporeal membrane oxygenation have been described, but data are limited.

**Antibiotic Prophylaxis and Vaccination**

Close patient contacts (household, nursery schools, daycare centers, military recruits, college dormitories, teammates) should receive antibiotic prophylaxis. Intimate contacts and health care workers with intimate exposure (eg, mouth-to-mouth resuscitation, intubation, or suctioning) should receive rifampin, 10 mg/kg (up to 600 mg) orally every 12 hours for four doses. The dose for neonates is 5 mg/kg. Patients should be warned that rifampin discolors the urine and secretions; contact lenses should be removed to avoid permanent staining. IM ceftriaxone (125 mg for children younger than 15 years old and 250 mg for those older than 12 years old) is effective and is an alternative for pregnant women and for people in whom compliance with an oral regimen cannot be ensured. Ciprofloxacin (500 mg orally) is another alternative for adults.

Meningococcal vaccine should be considered an adjunct to prophylaxis in epidemics and for close contacts in sporadic cases if one of the serotypes contained in the vaccine is identified as the causative agent. The currently available vaccines are quadrivalent vaccines containing for serogroups A, C, Y, and W-135. No vaccine is licensed for group B, a serogroup that causes a significant portion of meningococcal infection in the United States, but trials are currently under way. The conjugate vaccines (MCV4: Menactra and Menveo) produce a superior immune response compared to the polysaccharide vaccine (MPSV4: Menomune). Routine vaccination with MPSV4 is not recommended and should be limited to patients over 55 years old, or when MCV4 is unavailable. Routine vaccination with MCV4 is for persons 11 or 12 years old with a booster at 16 years old. Vaccination is also recommended for those at increase risk of meningococcal disease, including microbiologists who are routinely working with N. meningitidis, military recruits, children with functional or anatomic asplenia, people traveling to endemic areas of the world, such as sub-Saharan Africa.

**Disposition**

All patients with possible or confirmed meningococcemia should be placed in respiratory isolation and hospitalized, preferably in an ICU, because they can decompensate rapidly and without warning. A possible exception is the well-appearing child who has culture-proven N. meningitidis that has been taking appropriate antibiotics as an outpatient. This child should have a lumbar puncture performed to determine CSF involvement if one was not performed at the initial evaluation. Antibiotics should be continued on an inpatient basis, but an ICU may not be necessary if the child appears well.

**TOXIC SHOCK SYNDROME**

**Principles**

**Background**

TSS is a toxin-mediated systemic inflammatory response syndrome that was first described in 1978 in a series of seven children 8 to 17 years old who had high fever, rash, headache, confusion, conjunctival injection, edema, vomiting, diarrhea, renal failure, hepatic dysfunction, DIC, and shock. S. aureus was cultured from various body sites but not from the blood in five of the seven cases.

The disease gained notoriety in the early 1980s when many cases were reported in association with tampon use in young, healthy menstruating women. The term toxic shock syndrome was coined to describe the constellation of signs and symptoms. Investigators noted positive vaginal cultures for S. aureus, recurrence of illness during subsequent menses, and the value of
antistaphylococcal antibiotics in preventing recurrences. In response to the growing concern about TSS, changes were made to reduce the absorbency and composition of tampons. Non-menstrual cases were also recognized in both men and women as a result of a variety of predisposing conditions, and a case definition was published in 1982 (Box 121.6).

In the late 1980s, several reports described group A streptococcal infection associated with shock and multisystem organ failure. This is called *streptococcal toxic shock syndrome* because it shares many features with staphylococcal TSS. Box 121.7 shows the case definition for streptococcal TSS.

**Epidemiology**

The peak incidence of TSS occurred in 1980, when 890 cases were reported, 91% of which were associated with tampon use. Since then, the reduction in cases of the menstrual form of TSS has then, the reduction in cases of the menstrual form of TSS has occurred as a result of a variety of predisposing conditions, and a case definition was published in 1982 (Box 121.6).

Since the peak incidence of TSS occurred in 1980, when 890 cases were reported, 91% of which were associated with tampon use. Since then, the reduction in cases of the menstrual form of TSS has occurred as a result of a variety of predisposing conditions, and a case definition was published in 1982 (Box 121.6).

Non-menstrual staphylococcal TSS is associated with superinfection of various skin lesions, including burns, surgical sites, dialysis catheters, and lung (influenza-associated). It may also occur in association with staphylococcal respiratory infections or even with colonization by a toxigenic strain of the organism, without an obvious infectious source. Streptococcal TSS is classically associated with more severe soft tissue infections, such as necrotizing fasciitis and myositis, as well as with pneumonia, peritonitis, myometritis, and osteomyelitis.

The mortality rate from staphylococcal TSS has declined since the disease was first described. The case fatality rate in 1980 was 10% and is now 5%. Streptococcal TSS remains a highly fatal disease, with a mortality rate of 30% to 70%.

---

**BOX 121.6**

Case Definition of Toxic Shock Syndrome (Revised)

**CLINICAL CASE DEFINITION**

- Fever: Temperature $>102^\circ$F (38.9°C)
- Rash: Diffuse macular erythoderma
- Desquamation 1 to 2 weeks after onset of illness, particularly of palms and soles
- Hypotension: Systolic blood pressure $<90$ mm Hg for adults or below fifth percentile by age for children younger than 16 years old, orthostatic drop in diastolic blood pressure $>15$ mm Hg from lying to sitting, orthostatic syncope, or orthostatic dizziness
- Multisystem involvement—three or more of the following:
  - Gastrointestinal: Vomiting or diarrhea at onset of illness
  - Muscular: Severe myalgia or creatine kinase level at least twice the upper limit of normal for laboratory
  - Mucous membrane: Vaginal, oropharyngeal, or conjunctival hyperemia
  - Renal: BUN or creatinine at least twice the upper limit of normal for laboratory or urinary sediment with pyuria (>5 leukocytes/high-power field) in the absence of urinary tract infection
  - Hepatic: Total bilirubin, AST, and ALT at least twice the upper limit of normal for laboratory
  - Hematologic: Platelets <100,000/mm$^3$ or DIC, defined as prolonged clotting times, low fibrinogen level, and the presence of fibrin degradation products
  - Hepatic: Total bilirubin, AST, and ALT at least twice the upper limit of normal for laboratory, or a twofold increase in patients with preexisting liver disease
  - Acute respiratory distress syndrome: Defined by acute onset of pulmonary infiltrates and hypoxemia in the absence of cardiac failure or by evidence of diffuse capillary leak manifested by acute onset of generalized edema, or pleural or peritoneal effusions with hypoaalbuminemia
  - Generalized erythematous maculopapular rash that may desquamate
  - Soft tissue necrosis, including necrotizing fasciitis, myositis, or gangrene

**LABORATORY CRITERIA FOR DIAGNOSIS**

Negative results on the following tests, if obtained:
- Blood, throat, or CSF cultures (blood culture may be positive for *Staphylococcus aureus*).
- Rise in titer to Rocky Mountain spotted fever, leptospirosis, or rubeola.

**CASE CLASSIFICATION**

- **Probable**: A case that meets the laboratory criteria and in which four of the five clinical findings are present
- **Confirmed**: A case that meets the laboratory criteria and in which all five of the clinical findings are present, including desquamation, unless the patient dies before desquamation occurs

**BOX 121.7**

Case Definition of Streptococcal Toxic Shock Syndrome

**CLINICAL CASE DEFINITION**

- Hypotension: Systolic blood pressure $\leq 90$ mm Hg for adults or below fifth percentile by age for children younger than 16 years old
- Multisystem involvement—two or more of the following:
  - Renal: Creatinine $>2$ mg/dL (177 $\mu$mol/L) for adults or more than twice the upper limit of normal for age or more than twofold elevation above baseline for patients with preexisting renal disease
  - Hematologic: Platelets $<100,000/mm^3$ or DIC, defined as prolonged clotting times, low fibrinogen level, and the presence of fibrin degradation products
  - Hepatic: Total bilirubin, AST, and ALT at least twice the upper limit of normal for laboratory, or a twofold increase in patients with preexisting liver disease
  - Acute respiratory distress syndrome: Defined by acute onset of pulmonary infiltrates and hypoxemia in the absence of cardiac failure or by evidence of diffuse capillary leak manifested by acute onset of generalized edema, or pleural or peritoneal effusions with hypoaalbuminemia
  - Generalized erythematous maculopapular rash that may desquamate
  - Soft tissue necrosis, including necrotizing fasciitis, myositis, or gangrene

**LABORATORY CRITERIA FOR DIAGNOSIS**

- Isolation of group A streptococcus

**CASE CLASSIFICATION**

- **Probable**: A case that meets the clinical case definition in the absence of another identified cause of the illness and with isolation of group A streptococcus from a nonsterile site
- **Confirmed**: A case that meets the clinical case definition and with isolation of group A streptococcus from a normally sterile site (eg, CSF or joint, pleural, or pericardial fluid)

ALT, Alanine transaminase; AST, aspartate transaminase; BUN, blood urea nitrogen; CNS, central nervous system; CSF, cerebrospinal fluid; DIC, disseminated intravascular coagulation.
Etiology

Staphylococcal TSS is caused by colonization or infection with toxigenic strains of *S. aureus*, which produce toxic shock syndrome toxin 1 (TSST-1). *S. aureus* is present in virtually all cases of both forms of the illness. *S. aureus* has been isolated from the vagina or cervix in 98% of women with menstrual TSS, compared with a colonization rate of less than 10% of unaffected women. Because the organism is often not invasive, the blood cultures are often negative. Streptococcal TSS is caused by invasive infection with toxigenic strains of group A streptococcus.

Pathophysiology

The effects of various exotoxins produced by *S. aureus* and group A streptococcus cause the shock and multiorgan dysfunction associated with TSS. *S. aureus* produces TSST-1 and enterotoxin B. TSST-1 is identified in more than 90% of menstrual cases and 60% of non-menstrual cases. Other toxins may play a role in non-menstrual TSS. Antibodies to these toxins are protective in 60% of non-menstrual cases. Other toxins may play a role in non-menstrual TSS. Antibodies to these toxins are protective in 60% of non-menstrual cases.

Clinical Features

Symptoms and Signs

The clinical presentations of streptococcal TSS and staphylococcal TSS are similar. The primary difference is that an identifiable infectious source is virtually always present with streptococcal TSS, and colonization alone may be the source in staphylococcal TSS.

TSS should be considered in patients who present with fever, rash, hypotension, and evidence of end-organ damage, such as respiratory failure or altered mental status. Patients may have a prodromal illness with fever, chills, nausea, vomiting, watery diarrhea, headache, myalgias, and pharyngitis, which can last 2 to 3 days before progression to frank sepsis and organ dysfunction. Other patients may become abruptly symptomatic within hours. Rapid progression is more typical of streptococcal TSS. Patients may complain of pain at a site of infection more proportional to the degree of hypotension. Confusion, somnolence, agitation, and combativeness are present in 55% of patients with streptococcal TSS.

The fever is usually high and abrupt in onset, although septic patients may have hypothermia. The classic rash is a nonpruritic, diffuse, blanching, macular erythema. It develops in the first few days of the illness and may be faint, evanescent, and mistaken for the flush associated with a fever. It is usually diffuse but may be localized to the trunk, extremities, or perineum. After about a week, fine flaky desquamation occurs on the face, trunk, and extremities, followed by full-thickness peeling of the palms, soles, and fingers. This classic rash progression is much more common in staphylococcal TSS and is present in less than 10% of patients with streptococcal TSS. Patients with streptococcal TSS may have a scarlet fever–like rash, petechiae, or maculopapular lesions. Mucosal involvement may also occur, including conjunctival and scleral hemorrhages, “strawberry tongue,” and mucosal ulceration.

The patient’s mental status is frequently abnormal—out of proportion to the degree of hypotension. Confusion, somnolence, agitation, and combativeness are present in 55% of patients with streptococcal TSS and in even more patients with staphylococcal TSS.

Other findings on physical examination include pharyngeal and conjunctival erythema and peripheral edema. Vaginal mucosal erythema and purulent vaginal discharge may be present in menstrual TSS but are not required for the diagnosis to be made. As multiple organ systems become involved, a wide constellation of signs and symptoms may be seen. Gastrointestinal involvement is manifested by vomiting, diarrhea, and severe abdominal pain. Hepatomegaly may be present. Acute respiratory distress syndrome develops in more than half of patients and is manifested by rales on pulmonary examination and hypoxia. Comparisons between staphylococcal and streptococcal TSS are presented in Table 121.7.

NSAID, Nonsteroidal anti-inflammatory drug.
Complications

Complications of TSS include acute respiratory distress syndrome, shock, gangrene, DIC, and a constellation of neuropsychiatric symptoms. Renal failure occurs in 80% of patients but is irreversible in only 10%. Less common findings in staphylococcal TSS include rhabdomyolysis, seizures, pancreatitis, pericarditis, and cardiomyopathy. Women with the menstrual form of TSS may experience one or more recurrent episodes; recurrences of the non-menstrual form are rare. Complication rates are higher with streptococcal TSS. Rhabdomyolysis occurs in up to 63% of patients with streptococcal TSS and is usually related to the underlying soft tissue infections.

Diagnostic Strategies

Diagnosis of TSS does not require a positive culture for S. aureus, but isolation of Streptococcus organisms is a criterion. The case definitions (see Boxes 121.6 and 121.7) are useful, but they are neither specific nor foolproof.

No specific laboratory changes are associated with TSS, but many abnormalities are common. Leukocytosis or leukopenia can occur. A marked bandemia is common, and myelocytes and metamyelocytes may be seen. Elevated creatinine levels and hemoglobinuria occur in most patients. Renal dysfunction occurs before hypotension in half of the patients. Hypercalcemia (85%) and life-threatening hypocalcemia (79%) are prominent initially and persist throughout the course of the disease. Other abnormalities include anemia, thrombocytopenia, prolonged prothrombin and activated partial thromboplastin times, hyper-bilirubinemia, elevated transaminase levels, severe metabolic acidosis, and sterile pyuria. Creatine phosphokinase (CPK) levels may be elevated in patients with necrotizing fascitis and myonecrosis.

Blood cultures are positive for bacteria in 60% of cases associated with group A streptococcus but are rarely positive in staphylococcal TSS. Gram's stains and cultures from wounds may identify the organism. Culture of the cervix or vagina is positive in 90% of menstrual cases of TSS, even in the absence of local infection.

Chest radiography may reveal acute respiratory distress syndrome or a pulmonary source of the organism. Plain radiographs of any infected skin or soft tissue site typically show only soft tissue swelling but may reveal evidence of a retained foreign body or air in the soft tissue. A lack of air in the soft tissue does not rule out a necrotizing soft tissue infection.

An ECG may reveal evidence of ischemia, arrhythmias, and varying degrees of atrioventricular block in association with sepsis. A blood gas analysis may indicate metabolic acidosis secondary to hypotension or hypoxia. A lumbar puncture should be performed in febrile patients with altered mental status to evaluate for meningitis. It is prudent to wait for the results of a coagulation profile before the lumbar puncture is performed, because these patients may have DIC at presentation. The CSF is normal in patients with TSS.

Differential Diagnosis

The differential diagnosis of TSS includes any septic illness with exanthems. Other diseases to consider include heat stroke, cellulitis, Kawasaki disease, staphylococcal scalded skin syndrome, scarlet fever, drug reactions such as Stevens-Johnson syndrome, toxic epidermal necrolysis (TEN), Rocky Mountain spotted fever, clostridial gas gangrene, leptospirosis, meningococcemia, gram-negative sepsis, atypical measles, and viral illnesses.

Kawasaki disease occurs almost exclusively in children, usually does not progress to shock, lacks multisystem involvement, is manifested with a protracted fever, and is associated with thrombocytopenia later in its course. Staphylococcal scalded skin syndrome presents with a desquamating rash acutely, whereas the desquamation of TSS occurs in the convalescent phase. Staphylococcal scalded skin syndrome does not progress to shock, is not associated with multisystem illness, and lacks mucous membrane involvement. Scarlet fever differs in its clinical course by lack of shock and multisystem involvement, positive cultures for group A streptococcus, and a rise in the convalescent titer. Stevens-Johnson syndrome usually occurs after drug administration, has characteristic mucous membrane lesions, and lacks desquamation. TEN may be difficult to distinguish from TSS; TEN patients are typically febrile, are in shock, and can progress to multisystem failure. The desquamation of TEN occurs early in the course of the disease, and it usually occurs after administration of a drug.

Rocky Mountain spotted fever occurs after a tick bite, has a distinctive rash, and is associated with a severe headache without an altered mental status or hypotension. Leptospirosis occurs in endemic areas and may be distinguished by positive serologic studies and cultures. Petechiae and purpura occurring anywhere on the skin characterize the rash of meningococcemia.

Management

Patients with TSS should receive fluid resuscitation with crystalloids and may require up to 10 to 15 L/day. Supplemental oxygen should be provided to all septic patients, regardless of the initial pulse oximetry reading. This allows maximum tissue oxygenation and reduces acidosis. Patients should be placed in a monitored setting. Assisted ventilation may be necessary in patients with acute respiratory distress syndrome. The source of bacteria, such as tampons, nasal packs, and other foreign bodies, should be removed. Prompt surgical consultation should be obtained to débride wounds. If specimens are sent for culture, the laboratory should be informed of the suspected diagnosis. Patients who do not respond to fluid resuscitation require vasopressors, such as norepinephrine, dopamine, phenylephrine, and epinephrine.

Antibiotics should be initiated early in the treatment of TSS because the clinical presentation of the disease is similar whether the source is staphylococcal or streptococcal. For septic patients without an identified organism, broad-spectrum antibiotics should be administered. Although the penicillinase-resistant penicillins (nafcillin, oxacillin) have been widely used in the treatment of TSS, we recommend clindamycin as a first-line agent. Clindamycin is a potent suppressor of bacterial toxin synthesis; it also facilitates phagocytosis of streptococci by inhibiting M protein synthesis, decreases monocyte synthesis of cytokines, and has a longer postantibiotic effect than the β-lactams. The dose is 600 to 900 mg IV every 8 hours. (The pediatric dose is 20–40 mg/kg/day divided every 6 to 8 hours.)

Patients who do not respond to massive fluid resuscitation, antibiotics, and vasopressors should be considered for intravenous immune globulin (IVIG) treatment, especially if pulmonary edema develops and mechanical ventilation is required. Pooled immune globulin has high titers for antibodies to TSST-1 and other exotoxins, and significant improvement has been reported with its use in streptococcal TSS. Because the data in staphylococcal TSS are inconclusive, and the mortality is relatively low, immunotherapy should be reserved for life-threatening cases. If it is used, the recommended dose is 1 to 2 g/kg on day 1 administered intravenously during several hours, followed by 400 to 500 mg/kg/day for up to 5 days.

Hemodialysis or hemoperfusion may be necessary as more than half of streptococcal TSS patients develop renal failure. Both modalities may reduce concentrations of circulating toxins, and a study in Sweden demonstrated the lowest mortality rate ever recorded for strep TSS.
The value of corticosteroids in TSS is unresolved. They are not currently recommended for treatment of staphylococcal or streptococcal TSS but should be given to patients thought to have adrenal insufficiency related to underlying disease or chronic steroid use.

**Disposition**

All patients thought to have TSS should be admitted to an ICU. Prompt surgical consultation should be obtained for patients with a wound source.

**KEY CONCEPTS**

- All patients appearing septic should be treated with broad-spectrum antibiotics as soon as possible, even before a definitive diagnosis is made.
- A surgeon should be consulted as soon as possible for patients with sepsis and a débridable source of infection.
- Immunity to diphtheria, tetanus, and pertussis wanes significantly in adults. Pertussis should be considered a cause of persistent cough in adults. A tetanus vaccination history should always be obtained from patients with trauma or infection. When there is doubt about the history, the age-appropriate vaccine according to CDC guidelines is administered.
- Neonates with suspected pertussis should be admitted to an intensive care setting.
- Botulism should be kept in the differential diagnosis for the infant with failure to thrive, constipation, or decreased muscle tone and for the injection drug user with neurologic symptoms.
- Patients with pneumococcemia, meningococcemia, and TSS can decompensate rapidly. Antimicrobial therapy should be initiated promptly, before identification of an organism.

CHAPTER 121: QUESTIONS & ANSWERS

121.1. An 18-year-old male Hispanic immigrant presents with acute-onset sore throat, fever, and weakness. He has no past medical history. Examination is remarkable for a grayish white exudative coat over both tonsils and the posterior pharynx. There is modest neck swelling with cough, low-grade fever, and hoarseness. Rapid strep testing and monospot results are negative. Which of the following statements regarding this patient’s disease is true?
A. Emergent antibiotics and corticosteroids are the main therapy.
B. Neurornuscular examination is critical. C. Rapid treatment will obviate the need for intubation.
D. The electrocardiogram (ECG) is a sensitive indicator of myocarditis.
E. The highest mortality occurs in the presence of myocarditis.

Answer: B. Diphtheria can be a more benign upper respiratory/nasal infection or a “malignant” process with airway obstruction, myocarditis, and neuropathy (palate is involved first; the only cells spared are cortical). Antibiotics stop further organism growth, but diphtheria equine antitoxin is the key to therapy. Death is usually from myocarditis or airway obstruction, with the highest mortality seen in patients with the “bull neck” appearance. The ECG is an insensitive indicator of myocarditis.

121.2. An 11-year-old child presents with coughing paroxysms for 10 days. This was preceded by a mild upper respiratory tract infection. The paroxysms occur multiple times per day and have occasionally caused vomiting. The child is relatively well between episodes. There is no evidence of active infection. The calf is in active healing clean wound above the medial malleolus with subcutaneous air. Which of the following statements concerning the patient’s disease is true?
A. Antibiotics will shorten illness duration.
B. Erythromycin should be given to unimmunized contacts.
C. Fever is expected.
D. Thoracic petechiae should prompt a septic evaluation.
E. Throat culture is diagnostic.

Answer: B. Pertussis, caused by a gram-negative bacterium, is a three-phase illness: catarrhal (upper respiratory tract infection), paroxysmal, and convalescence of weeks to months. The coughing phase is characterized primarily by complications related to the paroxysms, such as subconjunctival hemorrhage, pneumomediastinum, headache, rectal prolapse, chest wall petechiae, and even seizures. Fever is rare unless there is secondary infection. Antibiotics only reduce the carrier state. Corticosteroids may help younger children. Antibiotic prophylaxis is indicated for nonimmunized contacts. Nasal culture is diagnostic. Standard cough suppressants are ineffective.

121.3. After which of the following circumstances has tetanus been reported?
A. Childbirth
B. Chronic skin ulcers
C. Corneal abrasion
D. Otitis media
E. All of the above

Answer: E. It has also been reported after dental procedures, abortions, and intestinal operations. In these cases, the source of the bacteria is endogenous because up to 10% of humans harbor Clostridium tetani in the colon.

121.4. Which of the following statements concerning the tetanus neurotoxin (tetanospasmin) is true?
A. A shorter incubation period portends a better prognosis.
B. It blocks presynaptic release of gamma-aminobutyric acid (GABA).
C. Sensory nerves are blocked, followed by motor nerves.
D. Synaptic binding is reversible and overcome by acetylcholinesterase therapy.
E. The autonomic nervous system is relatively spared.

Answer: B. The toxin migrates in the motor nerve from the injury site to the central nervous system (CNS). Presynaptic release of the inhibitory neurotransmitter GABA and glycine is diminished. The unopposed excitatory action results in muscle spasm. Presynaptic inhibition of the autonomic nervous system is also lost, and wide heart rate and blood pressure fluctuations are seen. The toxin binding is irreversible and diminishes only with axon synaptic regeneration. A shorter incubation period is a harbinger of a worse outcome.

121.5. A 62-year-old male farmer with no medical problems presents with leg pain and muscle spasms. He reports moderate to severe pain and muscle spasms in the calf that have occurred and worsened during 3 days. Two weeks prior, he suffered a puncture wound to his ankle just above his boot top with a piece of metal. Examination is remarkable for a heart rate of 115 beats/minute, blood pressure of 170/110 mm Hg, and a healing clean wound above the medial malleolus with no evidence of active infection. The calf is in active spasm with some increased tone in the peroneal musculature also. Which of the following statements regarding this patient’s disease is true?
A. A radiograph should be obtained to assess for subcutaneous air.
B. Admission for intravenous (IV) antibiotics is indicated.

Answer: A. A radiograph should be obtained to assess for subcutaneous air.
C. Lumbar spine magnetic resonance imaging (MRI) is indicated.
D. Outpatient management is indicated.
E. Tetanus immune globulin is indicated.

**Answer:** E. Localized tetanus reflects a local neuromuscular process with pain and spasm. It is likely due to a partial immunity. Immune globulin is indicated. Although mortality is lower, it can progress to generalized tetanus, and admission is warranted.

121.6. Generalized tetanus may be confused with which of the following conditions?
A. Malignant hyperthermia
B. Neuroleptic malignant syndrome
C. Organophosphate poisoning
D. Serotonin syndrome
E. Strychnine poisoning

**Answer:** E. Strychnine poisoning is the only clinical condition that mimics generalized tetanus. Strychnine, like tetanus toxin, antagonizes glycine release but has no gamma-aminobutyric acid (GABA) effect. Patients develop opisthotonos while remaining alert. The annual incidences of the two processes are similar. Serum and urine strychnine tests should be performed when tetanus is suspected.

121.7. Which of the following statements regarding botulism is true?
A. It does not affect the autonomic nervous system.
B. The gastrointestinal system is spared.
C. The syndrome may mimic Guillain-Barré syndrome onset.
D. The toxin has its primary effect at the spinal cord.
E. Urinary retention may occur.

**Answer:** E. The toxin blocks the presynaptic release of acetylcholine at peripheral and autonomic nerve junctions. This proceeds in a descending manner, ultimately resulting in both a muscarinic and a nicotinic anticholinergic syndrome with muscle weakness, cranial nerve dysfunction, and diffuse parasympathetic diminution with constipation, ileus, and urinary retention. The descending, “cranial nerve first” pattern is opposite the ascending Guillain-Barré syndrome picture. Orthostatic hypotension may be profound.

121.8. Which of the following statements regarding wound and food-borne botulism is true?
A. Incubation times are similar.
B. The sequence of neural involvement is different.
C. Wound botulism affects central nervous system (CNS) gamma-aminobutyric acid (GABA) tone.
D. Wound botulism does not have gastrointestinal involvement.
E. Wound botulism is more common.

**Answer:** D. Wound botulism also has a longer incubation period.

121.9. A 31-year-old man presents with double vision and difficulty swallowing. He has no medical history and takes no medication. Your examination is remarkable for bilateral ptosis, mildly dilated pupils, dry mucous membranes, difficulty swallowing, and weakness of the trapezius and deltoid muscles. Bowel sounds are absent. Vital signs are temperature, 97.3°F (36.3°C); heart rate, 93 beats/minute; blood pressure, 84/63 mm Hg; and respiratory rate, 20 breaths/minute. Which of the following is indicated?
A. Antitoxin
B. Blood cultures and antibiotics
C. Lumbar puncture
D. Magnetic resonance imaging (MRI) of the brain and spine

**Answer:** A. Botulism presents as a descending paralysis/anticholinergic syndrome. Autonomic dysfunction with orthostatic hypotension is common. Ileus and urinary retention may occur. Antitoxin, intensive care unit (ICU) admission, and early intubation are often indicated.

121.10. Fever and a nonblanching rash should suggest which of the following?
A. Disseminated tuberculosis
B. Meningococcemia
C. Plague
D. Pneumococcal sepsis
E. Tularemia

**Answer:** B. Up to 30% of meningococcemia patients will present with this picture and no immediate evidence of meningitis or sepsis.
CHAPTER 122
Viruses

Raghu Seethala | Sukhjit S. Takhar

PERSPECTIVE

The vast majority of viral infections, such as the common cold, are minor and self-limiting. However, some are highly pathogenic, contagious, and have the potential to cause devastating illness. In addition to century-old infections such as tuberculosis, there are also newer infections such as avian influenza, Middle East respiratory syndrome (MERS), and enterovirus D68 (EV-D68). With increased international travel occurring, emergency clinicians must be familiar with emerging infections that are spreading beyond their endemic origins. Patients are presenting to emergency departments (EDs) in the United States with infections traditionally thought to be tropical or foreign. In addition to recognizing symptoms and knowing the treatment for these infections, emergency clinicians should be familiar with isolation and reporting practices for the sentinel infections that can be vital to preventing global pandemics.

Advances in molecular biology have increased our knowledge of these infections, improved our diagnostic ability, and allowed more treatment options. Viruses are classified according to the type and structure of nucleic acid, capsid, and presence or absence of an envelope (Table 122.1). In practice, it is useful to group viruses based on clinical syndromes. This chapter reviews select viral illnesses that have high morbidity and mortality, those with specific treatments, and those that have major public health consequences. We begin by reviewing several preventable diseases that are reemerging because of decreasing immunization rates caused by largely unfounded fears of complications or side effects.

VACCINE-PREVENTABLE INFECTIONS OF CHILDHOOD

Childhood immunization is among the most important public health measures and has saved millions of children from serious illness, disability, and even death. An example of this is the eradication of smallpox in 1977. However, there has been a troubling trend of increasing nonmedical exemptions from mandated school-entry vaccines in developed nations, and routine immunizations have been rejected by some because of question of their safety and the lack of perceived threat for serious vaccine preventable diseases. The emergency clinicians may therefore play a significant role in educating parents as to the safety and efficacy of childhood immunizations. The U.S. Advisory Committee on Immunization Practices (ACIP), the American Academy of Pediatrics (AAP), and the American Academy of Family Physicians recommend a specific childhood immunization schedule each year. Table 122.2 summarizes the currently available viral vaccines and recommended schedule.

Mumps

Principles

Mumps is an RNA virus that is a member of the Paramyxoviridae family. It causes a febrile illness with swelling and tenderness of the parotid gland. Since the advent of the mumps vaccine in 1967, there has been a 99% decrease in the incidence of mumps in the United States. Despite the vaccine, recent outbreaks in developed nations, even in vaccinated individuals, raised concerns about resurgence of mumps. Mumps is spread via infected respiratory secretions that enter a susceptible respiratory tract. The incubation period is 16 to 18 days, ranging from 12 to 25 days. Infected patients are most contagious 1 to 2 days before onset of disease but can be contagious as early as 7 days before symptoms and up to 9 days after symptoms start.

Clinical Features

Parotitis, either unilateral or bilateral, is the hallmark of this infection, occurring in over 95% of symptomatic patients (Fig. 122.1). The other salivary glands are not as commonly affected. The symptoms usually begin with fever, malaise, and headache. About one-third of mumps infections are asymptomatic. Up to 30% of mumps infections cause orchitis, which usually occurs 1 week after the onset of parotitis and is more commonly seen in older individuals. Orchitis is usually unilateral but can occur in both testes in up to a third of the cases. There is a high incidence of cerebrospinal fluid (CSF) pleocytosis in patients with mumps, but less than 10% have symptomatic meningitis, and less than 1% have encephalitis. The mortality from mumps is very low, but the majority of morbidity and mortality associated with mumps occurs in the encephalitis cases.

Differential Diagnosis

During an outbreak, mumps can be easy to diagnose. Other viral infections that can cause parotitis (Epstein-Barr virus [EBV], parainfluenza, influenza A virus, coxsackievirus, adenovirus, parvovirus B19, lymphocytic choriomeningitis virus, and human immunodeficiency virus [HIV]), bacterial infections, facial cellulitis, and tumor are all other diagnoses that should be considered.

Diagnostic Testing

Mumps can be confirmed by detection of viral RNA, via reverse transcription polymerase chain reaction (RT-PCR), detection of the virus itself from clinical specimen, or detection of antibodies (immunoglobulin M [IgM] or fourfold rise in immunoglobulin G [IgG] between acute and convalescent serum specimen). This entails collecting a buccal or oral swab specimen for virus isolation and blood sample for serologic testing. Collecting samples early improves yield as virus isolation greatly diminishes beyond the first week of symptoms.

Management and Disposition

The mainstay of treatment is supportive care with antipyretics and analgesics. There is no specific antiviral treatment. Most of cases have a benign, self-resolving course and will not require admission to the hospital. In the hospital setting, these patients should have

</table>
Complications of measles include otitis media, laryngitis, tracheobronchitis, bronchiolitis, pneumonitis, severe diarrhea, and acute encephalitis. The virus itself can also cause pneumonia. Bacterial superinfection can also occur. The populations that are at high risk for severe disease or complications include children younger than 5 years old, adults older than 20 years old, pregnant women, and the immunocompromised.

Subacute sclerosing panencephalitis (SSPE) is a rare but fatal complication of measles. SSPE is a slow progressive infection of the central nervous systems (CNS) that results from a prior measles infection. It is thought to be due to continual measles infection of the CNS. The mean time of onset of SSPE is 7 years after measles infection. Symptoms include behavior change, decreased intellect, ataxia, and myoclonic seizures followed by...
progressive neurologic deterioration and death. Since the development of measles vaccine, this disease has almost disappeared in the United States.

**Differential Diagnosis**

Measles can be mistaken for other acute respiratory viral illnesses with rash or even noninfectious illnesses that present with fever and rash. Other diagnoses to consider include rubella, roseola, dengue, Kawasaki disease, and drug rash. Measles should be considered in patients that have travelled to endemic regions and return with fever and rash.

**Diagnostic Testing**

The diagnosis is usually made clinically, by visualizing both Koplik spots and the characteristic rash along with cough, coryza, and conjunctivitis. However, the disease is not common in the developed world, and it may be mistaken for other illnesses. Providers suspecting a diagnosis of measles should contact local health departments. They can be helpful in instructing practitioners to obtain the necessary samples for diagnosis and surveillance. The most common methods of confirmation are serologic testing for measles specific IgM antibody and detection of measles RNA by RT-PCR. For surveillance purposes, nasopharyngeal and urine samples can be obtained for virus isolation.

**Management**

The mainstay of treatment is supportive care. Bacterial superinfection should be treated appropriately. Post-exposure prophylaxis is important in individuals who do not have evidence of measles immunity and have a measles exposure, because it can provide protection or lessen the severity of disease. Post-exposure prophylaxis consists of either the measles, mumps, and rubella (MMR) vaccine within 72 hours, or immunoglobulin within 6 days. Healthy infants should receive 0.25 mL/kg of immunoglobulin intramuscularly, and immunocompromised children should be given 0.5 mL/kg intramuscularly, up to 15 mL. Children and the malnourished who are hospitalized with severe measles may benefit from vitamin A.

**Disposition**

Patients with measles require admission to the hospital based on the severity of illness. Uncomplicated measles patients should be treated at home to prevent spread of the disease. It is important, however, to observe appropriate isolation precautions in the hospital setting. Infected individuals should have airborne isolation for 4 days after they develop the rash.

**Rubella (German Measles)**

**Principles**

Rubella is a single stranded RNA virus that is a member of the Togaviridae family. Since the wide scale implementation of the vaccine, cases have dropped by greater than 99%. As a result, rubella is no longer considered endemic in the United States. The virus is spread via contact with respiratory droplets. In pregnant patients, the virus spreads to the placenta with subsequent infection of fetal organs.

**Clinical Features**

Acquired rubella is a mild febrile illness associated with a diffuse maculopapular rash, malaise, headache, and arthritis. Encephalitis and thrombocytopenia are rare complications. Rubella is generally a mild disease, but consequences in pregnant patients can be devastating. It can cause miscarriage, intrauterine death, prematurity delivery, or congenital rubella syndrome. Congenital rubella syndrome is characterized by severe birth defects, including hearing impairment, cataracts, retinopathy, mental retardation, microcephaly, and a variety of congenital heart defects.

**Diagnostic Testing**

The diagnosis of rubella on a clinical basis can be difficult because of the overlap with many other illnesses. Diseases that share common features include measles, roseola, erythema infectiosum (fifth disease), toxoplasmosis, and scarlet fever.

**Management and Disposition**

There is no specific antiviral treatment for rubella. The management centers on symptom control with antipyretics and analgesics. The course of this disease is short and benign. These patients can be treated at home for the most part.

**VIRAL INFECTIONS WITH VESICULAR RASH**

**Herpes Simplex**

**Principles**

Herpes simplex virus type 1 (HSV-1) and herpes simplex virus type 2 (HSV-2) are double-stranded DNA viruses of the Herpesviridae family. Herpes simplex infections primarily involve the skin or mucosal surfaces with occasional serious involvement of organs. Herpes simplex virus (HSV) infections range in acuity from asymptomatic to life-threatening. HSV-1 typically causes orofacial infections but can affect liver, lung, eye, genitalia, and the CNS. HSV-2 typically causes genital herpes but can also affect the CNS and other systems as well. HSV infections are common, the seroprevalence of HSV-1 has been reported to be 57.7% in persons aged 14 to 49 years old in the United States, and the seroprevalence of HSV-2 has been reported to be 17.0% in the same population.

Initial HSV-1 infection usually occurs in childhood. HSV gains entry via breaks in the skin or mucosal surfaces. Viral replication is then initiated in epidermal and dermal cells. The infection then spreads to the nervous system, where it lays latent in the sensory nerve ganglia. Any stressor such as emotional stress, trauma, intense sunlight, or fever can trigger reactivation of the virus. Recurrence rates are high for herpes infections. HSV-2 infections usually are acquired in adolescence or adulthood through sexual contact. Neonatal HSV-2 infections occur during childbirth via contact with the infected mother’s birth canal.

**Clinical Features**

**Oral Infection.** The first episode of HSV-1 infections usually occurs early in life and manifests as a gingivostomatitis and pharyngitis. Symptoms include fever, malaise, and vesicular lesions anywhere in the mouth or oropharynx. Infections can last between 10 to 14 days. Reactivation is usually much less severe and occurs as herpes labialis, small vesicles at the vermilion border
Viruses

like bacterial meningitis, brain abscess, other viral encephalitides, brain tumor, or stroke.

Genital Herpes. This infection is characterized by painful vesicles and ulcers on the external genitalia. The first infection is usually the most severe and can be accompanied by systemic symptoms like fever, headache, malaise, and myalgias. It is also common to have dysuria and tender inguinal lymphadenopathy. Infections can also spread to the perianal and rectal region as well.

Central Nervous System Infection. HSV-1 is a common cause of infectious encephalitis; it causes necrotizing hemorrhagic encephalitis, typically involving the temporal lobes. Herpes simplex encephalitis is characterized by acute onset of symptoms, including fever, headache, altered mental status, seizures, and focal neurologic deficits resulting from frontal and temporal lobe necrosis. If left untreated, mortality is greater than 70%. HSV-2 can cause meningitis in over 25% of patients with primary infection, more commonly in women. In contrast to HSV encephalitis, HSV meningitis has a benign course. Neonatal HSV encephalitis is caused by HSV-2 acquired during vaginal delivery of an infected mother.

Other Infections. Herpes can cause a variety of cutaneous manifestations. They typically present with the classic painful grouped vesicles on an erythematous base on the affected area. Herpetic whitlow is when this occurs on the finger. Herpes gladiatorum is a skin infection that can occur anywhere on the body and is associated with contact sports. Herpes can also cause ocular infections, including keratitis, conjunctivitis, and acute retinal necrosis. The immunocompromised patients are at risk for rare infections like HSV pneumonitis, esophagitis, or hepatitis.

Differential Diagnosis

When suspecting orofacial HSV infection, other considerations include other diseases with vesicles and ulcers, such as aphthous ulcers, coxsackievirus infections (herpangina and hand-foot-and-mouth disease), infectious mononucleosis, Stevens-Johnson syndrome, or Behçet’s disease. The differential diagnosis for genital herpes infection should include other sexually transmitted infections that have ulcers and vesicles, such as syphilis or chancroid or noninfectious diseases like Behçet’s disease. HSV encephalitis can be difficult to distinguish from other acute CNS emergencies like bacterial meningitis, brain abscess, other viral encephalitides, brain tumor, or stroke.

Diagnostic Testing

Oftentimes, clinicians will diagnose oral or genital HSV infections clinically given the classic appearance of the vesicles and ulcers. However, because of the stigmata and risk of transmission, testing should be performed if possible. Definitive diagnosis can be made by viral culture, direct fluorescent antibody (DFA), or polymerase chain reaction (PCR) from vesicles, ulcers, or mucocutaneous sites. PCR is more sensitive than viral culture. Tzanck smear has a low sensitivity and specificity and is mainly of historical interest.

The diagnosis of HSV encephalitis is made by PCR from the CSF. The routine laboratory tests sent after a lumbar puncture (LP) to assess for bacterial meningitis will not adequately assess for HSV encephalitis. Classically, CSF analysis will show an elevated white blood cell (WBC) count, with lymphocyte predominance. Depending on the degree of brain necrosis, an elevated red blood cell (RBC) count can also be seen. Although it is rare, CSF results can be normal in HSV encephalitis, particularly in immunocompromised individuals. This underscores the importance of waiting for PCR results before considering discontinuation of treatment in suspected cases of HSV encephalitis. In cases of negative CSF PCR with a high suspicion of HSV encephalitis, we recommend continuing empirical treatment and resending CSF PCR in 72 hours. Neuroimaging with computed tomography (CT) or magnetic resonance imaging (MRI) can be highly suggestive of HSV encephalitis, but imaging can be negative early in the course of illness (Fig. 122.5).

Management

Antiviral agents are the mainstay of treatment. The treatment dose and duration for herpes simplex depends on the clinical syndrome that is present. Acyclovir, valacyclovir, and famciclovir are the commonly used antiviral drugs with activity against HSV. These
drugs are nucleoside analogues that work by inhibiting viral DNA synthesis. Acyclovir is the only agent that is available in an intravenous (IV) formulation.

**Herpes gingivostomatitis or labialis**: First episodes are treated with oral acyclovir 200 mg five times a day (alternative regimen: 400 mg three times a day), valacyclovir 1 g twice daily, or famciclovir 250 mg three times a day for 7 days. Recurrent infections are treated with acyclovir 400 mg five times a day for 5 days, valacyclovir 2 g twice daily for 1 day, or famciclovir 1500 mg as a single dose.

**Genital herpes**: First episodes are treated with oral acyclovir 200 mg five times a day (alternative regimen: 400 mg three times a day), valacyclovir 1 g twice daily, or famciclovir 250 mg three times a day for 7 to 10 days. A shorter course is usually adequate for treatment of recurrence. For suppression of recurrent episodes, acyclovir 400 to 800 mg twice daily or valacyclovir 500 mg daily can be used.

**Herpetic whitlow and other mucocutaneous manifestations**: Administer acyclovir 200 mg five times a day or 400 mg three times a day for 5 days.

**Herpes keratitis**: Administer acyclovir 400 mg five times a day. Valacyclovir and famciclovir are probably also effective but have not been studied in clinical trials. If used for keratitis, we recommend using herpes zoster dosing. Topical antiviral therapy with trifluridine, acyclovir, or ganciclovir are all equally effective.

**HSV encephalitis**: Administer IV acyclovir 10 mg/kg every 8 hours for 14 to 21 days. Given the high mortality associated with this condition, antiviral therapy should be started as soon as the diagnosis is suspected. We recommend empirically treating all patients that are being ruled out for bacterial meningitis as well, because there is such overlap with the clinical presentation.

**Disposition**

The majority of herpes infections can be treated with oral antiviral therapy on an outpatient basis. Patients that are immunocompromised and have severe mucocutaneous disease or disseminated disease will benefit from inpatient admission with IV acyclovir treatment. All patients with suspected encephalitis should be admitted for empirical treatment and diagnostic results. Intensive care unit (ICU) admission may be necessary depending on the severity of neurologic symptoms. For HSV encephalitis patients, we recommend early involvement of infectious disease consultants to help guide treatment and neurology for management of cerebral edema and severe neurologic symptoms.

**Varicella-Zoster Virus**

**Principles**

The varicella-zoster virus (VZV) is another double-stranded DNA virus that is a member of the Herpesviridae family. VZV causes two common infections: varicella (chicken pox) and zoster (shingles). Transmission occurs via the respiratory tract through respiratory droplets and also by direct contact with virus present in the fluid-filled vesicles that occur with this disease. VZV initially infects the nasopharynx and spreads to the lymphoid tissue. The virus present in vesicles that develop on the skin then infects the nerve endings in the skin and travels to the dorsal ganglia where it lays latent.

Primary infection of VZV occurs as varicella (chicken pox). Varicella is highly contagious and occurs year round with a predilection for winter and spring months. Prior to the development of the varicella vaccine in 1995, most people would develop this infection in childhood. After widespread uptake of the vaccine the incidence of varicella has decreased by 90%, with subsequent decline in mortality. Zoster (shingles) is a result of reactivation of the latent virus. Risk factors for developing shingles include older age and immunosuppression.

**Clinical Features**

**Varicella.** Chicken pox is a febrile illness characterized by malaise and rash. The rash begins first on the scalp and face and then spreads to the trunk and extremities. The lesions start as maculopapular, and progress to fluid filled vesicles that eventually crust over and form scabs (Fig. 122.6). The lesions occur as crops at various stages of development. Patients are contagious until all lesions are scabbled over, which can typically take 1 to 2 weeks.

For the most part this disease has a benign course. Adults have a more severe course than children. The most common complication is a secondary bacterial infection of the skin lesions. VZV has been associated with invasive group A streptococcal infections and necrotizing fasciitis. Immunocompromised patients are at risk for disseminated disease and visceral organ involvement. Pregnant patients are also at risk for severe disease. Varicella pneumonia accounts for most of the morbidity related to this disease. Neurologic complications are rare but can include encephalitis, aseptic meningitis, transverse myelitis, and Reye syndrome. Although exceedingly rare, it is important to recognize the association of aspirin use with Reye syndrome, a progressive encephalopathy.
Herpes occurs in immunocompromised patients.

Disseminated zoster involving multiple dermatomes can cause nerve palsy, pain, and vesicular rash on the ear and in the auditory canal. Herpes zoster ophthalmicus (Ramsay Hunt syndrome) is characterized by facial nerve palsy, pain, and vesicle on the tip of the nose, has been associated with ocular involvement. Herpes zoster typically causes a vesicular rash with an erythematous base that occurs unilaterally in a single dermatome (Fig. 122.7). The rash is very painful and is often preceded by paresthesias or hypesthesia. In immunocompetent individuals, the rash will crust in 7 to 10 days and at that time patients are no longer contagious. Post-herpetic neuralgia, defined as pain that persists for more than 90 days, is the feared complication. Risk factors for post-herpetic neuralgia include older age and severity of pain at onset.

Zoster. Herpes zoster typically causes a vesicular rash with an erythematous base that occurs unilaterally in a single dermatome (Fig. 122.7). The rash is very painful and is often preceded by paresthesias or hypesthesia. In immunocompetent individuals, the rash will crust in 7 to 10 days and at that time patients are no longer contagious. Post-herpetic neuralgia, defined as pain that persists for more than 90 days, is the feared complication. Risk factors for post-herpetic neuralgia include older age and severity of pain at onset.

Diagnostic Testing

The majority of chickenpox and shingles diagnosis is made clinically. Confirmatory diagnosis can be made through viral culture, DFA, or PCR testing of the vesicle fluid.

Management

Varicella. The management is mainly supportive care with antipyretics and antihistamines to decrease the pruritus caused by the skin lesions. Aspirin should be avoided in children because of the association with Reye's syndrome. Antiviral therapy with acyclovir has been shown to decrease duration of fever and total number of lesions in healthy children but not reduce the number of varicella related complications. Therefore, we do not recommend treatment of otherwise healthy children with varicella. We recommend treating groups at high risk for varicella complications with acyclovir, including those older than 12 years old, adults, pregnant patients, persons with chronic cutaneous or pulmonary disorders, persons on long-term salicylate therapy, persons on aerosolized corticosteroids, and immunocompromised patients. The treatment should be initiated within 24 hours after the rash appears for the most benefit. The dose of acyclovir for VZV treatment is higher than that of HSV, 800 mg orally four times a day for 5 days. If the patient is immunocompromised and has severe disease, IV acyclovir should be administered.

Zoster. The goals of treatment for zoster are to treat the viral infection and control the pain that occurs with the rash. Uncomplicated zoster in the immunocompetent host can be treated with the following regimens for 1 week: acyclovir 800 mg five times a day, famciclovir 500 mg three times a day, or valacyclovir 1 g three times a day. Antiviral treatment should be initiated within 72 hours of onset of rash, because the efficacy beyond 72 hours is unclear. Immunocompromised patients should be treated regardless of time of onset of rash. Zoster involving more than one dermatome or disseminated zoster should be treated with IV acyclovir. The disease is often very painful and requires opioid agents. Currently there are no treatments that have reliably shown a reduction in the occurrence of postherpetic neuralgia. Antiviral treatment has shown mixed results in preventing postherpetic neuralgia. Corticosteroids have been studied extensively, but the latest Cochrane review did not support their use in preventing postherpetic neuralgia.

Disposition

Most patients with varicella and zoster can be treated at home. Patients with varicella are highly contagious and should be instructed to avoid people who have not fully been vaccinated or never had the disease, immunocompromised persons, or pregnant individuals until all of their lesions have crusted over. Immunocompromised patients, patients with disseminated zoster, or patients with complications will generally require admission to the hospital. In general, patients with varicella should be under contact and airborne precautions until all of the lesions have crusted over. An immunocompromised localized zoster patient only requires standard precautions, whereas an immunocompromised or disseminated zoster patient is treated like patient with varicella, requiring contact and airborne precautions.

VIRAL INFECTIONS CAUSING NONSPECIFIC FEBRILE ILLNESS

Epstein-Barr Virus

Principles

EBV is a member of the Herpesviridae family. It is classically known for causing infectious mononucleosis. It is also associated with several types of cancer, including Burkitt’s lymphoma, nasopharyngeal carcinoma, Hodgkin’s disease, and B cell lymphoma. EBV is ubiquitous with most individuals testing positive for antibodies by adulthood. One study demonstrated that 50% of 6- to 8-year-olds had antibodies to EBV, whereas 89% of 18- to 19-year-olds tested positive. EBV is spread via salivary secretions. The virus infects the oropharynx and then spreads through the bloodstream and infects B lymphocytes. There is a resultant proliferation of infected B lymphocytes and T lymphocytes, which leads to enlargement of lymphoid tissue.

Clinical Features

EBV infection in young children is usually asymptomatic or presents as mild pharyngitis. Adolescents and young adults tend to have the classic infectious mononucleosis (fever, exudative
pharyngitis, lymphadenopathy, myalgias, and fatigue). Splenomegaly is common—seen in up to 50% of cases. Hepatomegaly and jaundice occur less than 10% of the time. The symptom duration is typically 1 to 3 weeks, with some cases having malaise and fatigue for several months. Splenic rupture is rare, occurring in less than 0.5% of patients. It should be suspected in patients with left upper quadrant pain and is more common during the first 3 weeks of illness. Airway obstruction occurs in less than 5% of children with mononucleosis and is one of the common causes of hospital admission. Rare neurologic complications include encephalitis, aseptic meningitis, transverse myelitis, Guillain-Barré syndrome, retrobulbar neuritis, and peripheral neuropathies. Patients treated with amoxicillin or ampicillin for presumed streptococcal pharyngitis develop a nonallergic maculopapular rash.

Differential Diagnosis

EBV causes 90% of infectious mononucleosis; the remaining is caused by cytomegalovirus (CMV). Acute HIV infection, streptococcal pharyngitis, toxoplasmosis, and other causes of viral pharyngitis should all be considered in potential mononucleosis patients.

Diagnostic Testing

It is difficult to diagnose mononucleosis based on history and physical examination alone. Laboratory data can help confirm the diagnosis. Historically, the heterophile antibody test (monospot) has been the test of confirmation for primary EBV infection. The test has sensitivity ranging from 63% to 84% and specificity ranging from 84% to 100%.1 The test is often not positive in younger children. The WBC count typically demonstrates lymphocyte predominance, and atypical lymphocytes can sometimes be seen on peripheral smear. A lymphocyte count less than 4 × 10^9/L in adults has been shown to be highly predictive of a negative monospot test.12 Health care providers can test for antibodies to EBV viral capsid and nuclear antigen if the aforementioned testing is equivocal.

Management

Infectious mononucleosis typically has a self-limiting course. The treatment is supportive care with rest, antipyretics, and analgesia. Glucocorticoids have been used to decrease severity of symptoms, but there is insufficient evidence to support this practice. Antiviral treatment with acyclovir has not been shown to be effective in reducing the clinical symptoms of the disease. It is important to advise patients to avoid contact sports for at least 3 weeks to avoid the feared complication of splenic rupture. Abdominal ultrasound for assessment of spleen size may have a role in determining when it is safe to return to sports.13

Disposition

The majority of patients will be treated at home. Admission is necessary in those with airway obstruction and in patients with significant complications, like splenic rupture.

Cytomegalovirus

Principles

CMV is a double-stranded DNA virus that belongs to the Herpesviridae family. Depending on geographic location, the seroprevalence ranges from 45% to 100%.14 The spectrum of illness caused by CMV ranges from asymptomatic to severe disseminated disease in the immunocompromised patient. CMV is particularly harmful in pregnant patients, because it can lead to congenital infection, causing profound neurologic defects and permanent hearing loss. CMV is present in breast milk, saliva, feces, urine, semen, cervical secretions, and blood. The virus spreads via prolonged exposure to these body fluids. After primary infection, CMV establishes a lifelong latent infection.

Clinical Features

The primary CMV infection is subclinical in most individuals. Some immunocompetent adults will develop a mononucleosis-like syndrome. The illness can last from 2 to 6 weeks and is characterized by fever, fatigue, malaise, myalgia, and headache. Unlike EBV mononucleosis, the exudative pharyngitis and lymphadenopathy are less common. Although it is rare, CMV can cause severe disease in the immunocompetent individual. CMV colitis and CNS infection (meningitis, encephalitis, transverse myelitis) are the most frequent sites of severe CMV infection in the immunocompetent host. Up to one-third of critically ill immunocompetent patients have evidence of CMV reactivation.

The majority of newborns who are infected with congenital CMV appear healthy or normal at birth. Common problems caused by congenital CMV infection include premature birth, intrauterine growth retardation, microcephaly, seizures, thrombocytopenia, hepatosplenomegaly, or pneumonia. Sequelae of congenital CMV infection can present up to 2 years after birth. Frequent complications that occur are hearing loss, neurologic impairment, and ocular disturbances.

CMV can cause a serious, life-threatening disease in immunocompromised patients. CMV infection occurs in over 40% of solid organ transplant patients during the first 3 months when immunosuppressive therapy is the strongest. Transplant patients that are CMV seronegative and receive a CMV seropositive donor are at highest risk. HIV patients with CD4 count less than 100/µL are at high risk of CMV infection as well. In the immunocompromised host, CMV manifests initially as fever, malaise, and myalgias. The infection can then progress to cause leukopenia, pneumonia, esophagitis/gastritis, hepatitis, colitis, encephalitis, polyradiculopathy, and retinitis. CMV retinitis is the most common cause of blindness in HIV patients.

Differential Diagnosis

It is difficult to make the diagnosis of CMV infection solely on a clinical basis. Infectious mononucleosis caused by EBV presents very similarly. In the perinatal phase, infants with apparent infections should be evaluated for the other common congenital infections: toxoplasmosis, rubella, herpes simplex, syphilis, VZV, and parvovirus B19. Because the CMV infection can cause a wide array of disease in the immunocompromised host, the differential diagnosis should be broad and include other viral pathogens, bacterial infections, Pneumocystis infection, and fungal infections.

Diagnostic Testing

It is unlikely to make this diagnosis in the ED. Confirmation of this diagnosis centers on either virus isolation, serologic testing, or histopathology. Common methods involve PCR, viral culture, or antibody testing. The WBC count may show lymphocyte predominance with more than 10% atypical lymphocytes, much like EBV infections.

Management

For the most part, CMV infection in the immunocompetent host only requires symptomatic care for the mononucleosis-like
syndrome. The treatment recommendations for critically ill immunocompetent patients with CMV infection are less clear.\textsuperscript{13,16} Immunocompromised patients with CMV infection are treated more aggressively. Antiviral treatment is necessary in sight and life-threatening infections.

Ganciclovir is an IV agent that is used to treat CMV infections. The treatment for CMV retinitis is induction therapy: 5 mg/kg/dose every 12 hours for 14 to 21 days followed by 5 mg/kg/dose once daily maintenance therapy for a prolonged course. Fever, diarrhea, and thrombocytopenia are common adverse reactions. Valganciclovir is an oral prodrug that is metabolized to ganciclovir. The treatment regimen is induction: 900 mg twice daily for 21 days followed by maintenance of 900 mg once daily. Foscarnet and cidofovir are IV agents used to treat CMV resistant to ganciclovir, and both can also be used to treat HSV resistant to acyclovir. The main limiting toxicity of these drugs is renal impairment.

Disposition

Most immunocompetent patients with CMV infection can be managed at home. In contrast, immunocompromised patients with CMV infection will usually require admission to the hospital and depending on the extent of end organ damage may require ICU admission. Only standard precautions are required to care for these patients.

Enteroviruses

Principles

Enteroviruses are a group of single-stranded RNA viruses that are able to multiply within the gastrointestinal tract. Most infections are asymptomatic or mild undifferentiated illnesses. Despite their name, their major manifestation is not gastroenteritis. There are a multitude of enteroviruses; common ones include poliovirus, coxsackievirus A and B, echovirus, and enterovirus. These viruses are found globally and are transmitted via the fecal-oral route. Vaccination exists for poliovirus; and in the United States and other developed nations, the disease has been declared eradicated.

Clinical Features

Most of the infections caused by enteroviruses are asymptomatic or self-limiting febrile illnesses. More of the severe infections are discussed in the following sections.

Poliovirus. The poliovirus causes a nonspecific febrile illness with malaise, myalgias, headache, and sore throat. The most feared presentation of the poliovirus infection is paralytic poliomyelitis. This manifests as aseptic meningitis followed by back, neck, and muscle pain then the development of motor weakness. The paralysis is usually asymmetric, and affects proximal muscles more. Usually some recovery of motor function occurs months later, but approximately two-thirds of patients have some form of permanent weakness.

Non-Polio Enteroviruses. Most enterovirus infections are subclinical, but they can also cause a variety of symptoms and syndromes. Enteroviruses account for most causes of viral meningitis and encephalitis. Pericarditis and myocarditis are commonly caused by enteroviruses, particularly coxsackievirus B. Symptoms usually include chest pain, fever, dyspnea, and can progress to severe heart failure. Enteroviruses are a common cause of viral exanthems as well. Herpangina is caused by coxsackievirus A and presents with fever, sore throat, odynophagia, and vesiculopapular lesions on the cheeks and soft palate (Fig. 122.8).

Hand-foot-and-mouth disease is caused by coxsackievirus A or enterovirus 71 and commonly manifests as fever and malaise, followed by vesicles in the mouth, and vesicles on the hands and feet (Fig. 122.9). Pleurodynia is a painful illness characterized by fever and spasms of the chest wall and abdomen that occur in paroxysms.

In 2014, there was an outbreak across the United States of EV-D68.\textsuperscript{17} The virus affected mostly children and was severe in children with asthma. Typically EV-D68 causes mild respiratory illness, rhinorrhea, sneezing, cough, and myalgias but occasionally causes severe disease with wheezing and respiratory distress. There has also been an association with flaccid paralysis with anterior myelitis with EV-D68 infection.\textsuperscript{18}

Differential Diagnosis

Clinicians should consider other diagnoses depending on the specific symptoms and syndrome caused by enterovirus infection. For the diseases with skin and oropharyngeal lesions, herpes simplex, aphthous stomatitis, mononucleosis, and bacterial pharyngitis should be considered. The diseases with primary neurologic manifestation will present similarly to bacterial meningitis, and other causes of viral meningitis or encephalitis, including herpes simplex encephalitis. Myopericarditis can present similar to pulmonary embolism, myocardial infarction, or pneumonia.

Diagnostic Testing

Diagnosis is confirmed by viral culture, serology, or PCR. Samples can be sent from nasopharynx or oropharynx via swabs or washings, CSF, serum, stool, or pericardial fluid. Other diagnostic testing should be tailored toward the symptoms, such as ECG, chest x-ray, and cardiac biomarkers for evaluation of myopericarditis. If safe, LP should be performed for meningitis or encephalitis evaluation.

Management

The treatment is primarily symptomatic, because there are no specific antiviral therapies for enteroviruses that are currently recommended. Hand-foot-and-mouth disease can cause severe dehydration, because children will refuse to eat secondary to the painful lesions in the mouth. This illness is typically treated with
Influenza is an RNA virus from the Orthomyxoviridae family that causes acute respiratory symptoms. This virus is highly contagious and is transmitted through large particle respiratory droplets. Transmission usually requires close contact between individuals less than 1 meter apart. Epidemics and outbreaks occur almost annually, with the peak influenza activity usually occurring in the winter months in the United States. Influenza occasionally causes devastating pandemics. During the 1918 influenza pandemic, approximately 50 to 100 million people were killed across the globe. The most recent pandemic occurred in 2009, when a new strain of the H1N1 influenza emerged.

There are three major types of influenza: A, B, and C. The majority of human infections are caused by influenza A and B. Influenza can be further subdivided based on the two major surface glycoproteins present, hemagglutinin (H) and neuraminidase (N). Influenza A is responsible for most of the severe epidemics and pandemics because of its ability of surface antigens to undergo periodic changes. This is known as antigenic drift when the changes are minor and antigenic shift when the changes are major.

**Clinical Features**

Influenza typically presents as fever with constitutional (headache, malaise, and myalgias) and respiratory symptoms (cough, sore throat, rhinitis). These symptoms typically last for 3 to 7 days. Individuals are usually contagious 1 day prior to symptom onset and up to 1 week after. The majority of influenza is a benign self-limited disease. Patients with following conditions are at risk for severe influenza and influenza related complications (Box 122.1). The common influenza related complications are bacterial...
pneumonia (typically due to Staphylococcus aureus), sinusitis, and otitis media. Influenza can also assert its pathogenic effects by exacerbating underlying cardiopulmonary and other chronic health conditions. Occasionally influenza itself can cause a rapidly progressing pneumonia that leads to acute respiratory distress syndrome (ARDS).

Differential Diagnosis

The differential diagnosis is broad, because many different infectious diseases can present with similar symptoms. Other respiratory viruses like RSV, rhinovirus, or coronavirus can have a similar presentation. Additionally bacterial infections like pneumonia and meningitis can present similarly.

Diagnostic Testing

Influenza can be diagnosed clinically based on the signs and symptoms, especially during influenza season, but the accuracy of clinical diagnosis in the absence of supportive tests is not high because influenza shares common features with many viral and bacterial infections. Clinical diagnosis alone yields a sensitivity of 62% to 65% and a specificity of 63% to 67%. There are several diagnostic tests available to the emergency clinician. Rapid influenza diagnostic tests are based on immunochromatographic assays that detect specific influenza antigens, yielding results in less than 30 minutes. The sensitivity of these tests can vary from 50% to 70%, with specificities above 95%. Confirmatory tests are viral culture and RT-PCR. Viral cultures can take 3 to 10 days to result and are not useful in the emergency setting. RT-PCR can take between 1 to 6 hours to result and can be useful if there is a high suspicion of influenza, and confirmation of diagnosis will change management.

Management

The management of influenza centers on symptom control with antipyretics, analgesics, and hydration. There are several antiviral agents that are available to treat influenza, but there is some controversy surrounding treatment with these agents.

Neuraminidase Inhibitors. Oseltamivir, zanamivir, and peramivir are the currently available neuraminidase inhibitors. They work by inhibiting the release of viral progeny from infected cells. These drugs are active against both influenza A and B.

Oseltamivir is available orally as a capsule or suspension. The treatment dose in adults and children weighing more than 40 kg is 75 mg twice daily for 5 days. For children younger than 1 year old, the dose is 3 mg/kg twice daily. For children 1 year or older, the dose varies by weight: for those weighing less than or equal to 15 kg the dose is 30 mg twice daily, for those weighing 15 to 23 kg it is 45 mg twice daily, and for those weighing 23 to 40 kg it is 60 mg twice daily. The dosing does require adjustment in renally impaired patients based on creatinine clearance. The main side effects reported have been nausea and vomiting.

Zanamivir is available as an aerosol powder and is administered via inhalation through a specialized inhaler and is approved for use in patients 7 years old and older. The treatment dose is two inhalations twice daily for 5 days. It is not recommended in patients with underlying asthma and chronic obstructive pulmonary disease (COPD), because it can cause bronchospasm.

Peramivir is the first IV neuraminidase inhibitor available for treatment in influenza patients. It gained U.S. Food and Drug Administration (FDA) approval in December of 2014. The treatment dose is 600 mg IV administered once as a single dose.

Adamantane Antivirals. Amantadine and rimantadine are the currently available adamantane antivirals. They prevent or greatly reduce the uncoating of the viral RNA of influenza A after attachment and endocytosis by host cells. They have no activity against influenza B. In the past, they have been used for prophylaxis and treatment for influenza A. In recent years, the circulating influenza strains have demonstrated greater than 90% resistance to these drugs. Therefore they are not currently recommended for use for influenza treatment.

The controversy surrounding use of neuraminidase inhibitors (NIs) has centered on its modest effect with treatment. The most recent Cochrane review found that oseltamivir reduced symptom duration by 16.8 hours in those treated within 48 hours of symptom onset, but it had no effect on hospitalization or reduction of severe influenza complications. However, another recent meta-analysis found that treatment with oseltamivir was associated with accelerated symptom improvement, reduction of risk in lower respiratory tract complications, and decreased admission to hospital.

Investigations have also found that treatment of hospitalized patients with NIs is associated with reduction in mortality. The greatest benefit is in very early treatment (within 6 hours of symptoms onset), but some studies have demonstrated benefit up to 5 days after symptoms onset in hospitalized patients. The Centers for Disease Control and Prevention (CDC) recommendations are to treat all patients as early as possible who are hospitalized, have severe illness, or are at risk for influenza related complications. The patient population at risk for influenza related complications is listed in Box 122.1.

Disposition

The majority of patients with influenza are discharged home with symptomatic treatment instructions, although this depends on the specific virulence of the circulating strain of the season. Patients with severe influenza require admission. These patients usually have accompanying cardiopulmonary comorbidities. A prospective study in the ED demonstrated that only 6% of patients with culture or PCR confirmed influenza were hospitalized. A small number of influenza patients will require ICU admission because of primary influenza or acute exacerbation of an underlying illness. Influenza can cause rapidly progressive ARDS with refractory hypoxemic respiratory failure. These patients with rapidly progressive ARDS may benefit from transfer to centers that perform extracorporeal membrane oxygenation (ECMO). During the 2009 H1N1 pandemic, some centers had success with managing ARDS patients on ECMO.

Coronavirus

Principles

Coronaviruses are single-stranded RNA viruses that cause respiratory illness. There are several strains known to occur in humans with most of them causing the common cold. Severe acute respiratory syndrome–coronavirus (SARS-CoV) is a particularly virulent coronavirus that first appeared in China in November 2002. SARS-CoV caused the severe acute respiratory syndrome (SARS). SARS affected at least 8,098 individuals in 29 countries across Asia, Europe, and North and South America. Most of the cases were from China and Hong Kong, with a mortality rate near 10%. Since 2004, there have not been any reported cases of SARS. The incubation period for SARS-CoV is typically between 3 to 10 days. SARS is transmitted through close contact with infected individuals via respiratory droplets. The virus can also be transmitted by touching a surface contaminated with infectious secretions. Patients are considered contagious for up to 10 days after resolution of fever if respiratory symptoms are improving.
In 2012, another novel coronavirus causing international concern emerged called Middle East respiratory syndrome–coronavirus (MERS-CoV). The majority of cases have been reported from Saudi Arabia and United Arab Emirates, but cases have been reported in the United States, Europe, and Asia. All reported cases have been associated with direct or indirect exposure to travel or residence in the following countries: Saudi Arabia, the United Arab Emirates, Qatar, Jordan, Oman, Kuwait, Yemen, Lebanon, and Iran.\(^a\)

This virus has a high mortality rate and shares many features with SARS-CoV. The mode of transmission has not fully been elucidated yet, but the most likely route is via direct aerosol transmission. It is unclear how contagious MERS-CoV is. There have been case reports of transmission in the health care setting via a less than 10-minute encounter, maintaining 3 feet distance, but without any personal protective equipment (PPE).\(^a\) On the other hand, investigations have also revealed no transmission among close contacts.\(^a\) The reported incubation time for MERS-CoV is between 5 to 14 days.

Clinical Features

**Severe Acute Respiratory Syndrome.** SARS initially causes high fevers, malaise, myalgias, chills, and rigors. This is followed by cough, shortness of breath, tachypnea, and pleuritic pain. Sore throat and fever are less commonly manifested in SARS, and diarrhea can occur later in the course of the disease. Close to one-third of patients will have improvement in symptoms after the initial febrile illness. Approximately 20% to 30% go on to have abnormalities at some point during the course of illness. Over 80% of MERS patients have abnormalities on chest x-ray ranging from subtle findings to extensive bilateral infiltrates.\(^a\)

**Management**

There is no specific antiviral treatment for coronavirus infections, including SARS and MERS. The mainstay of treatment is supportive care. For the benign URI, nothing more than rest, antipyretics, and analgesics are needed. On the other hand, patients with SARS and MERS may require more invasive supportive measures. The diagnosis of SARS or MERS will not be immediately apparent, so they should be initially treated with antibiotics covering community acquired or health care–associated pneumonia. If mechanical ventilation is required, they should be ventilated according to the ARDSNet strategy with low tidal volumes to further limit lung injury.

Prevention of transmission is an important component of SARS and MERS management. This involves early identification of cases and prompt isolation of suspected cases. Obtaining an accurate travel history in all febrile patients with a respiratory illness is key to early identification of cases of SARS and MERS.

Nosocomial outbreak was a critical component of the 2003 SARS outbreak. CDC guidelines on infection control measures for these infections can be found at [www.cdc.gov/sars/infection/index.html](http://www.cdc.gov/sars/infection/index.html) and [www.cdc.gov/coronavirus/mers/infection-prevention-control.html](http://www.cdc.gov/coronavirus/mers/infection-prevention-control.html).

**Disposition**

Most patients with coronaviruses can be treated at home. Patients with SARS may require admission to the hospital, with up to 30% requiring ICU care. MERS patients have a case fatality rate of 35% and will likely require admission to the hospital and ICU, depending on severity of illness. Patients with suspected SARS and MERS should be properly isolated with contact precautions and airborne isolation. The hospital infection control team and department of public health should be notified immediately for patients under investigation for SARS and MERS.

**Rhinovirus**

**Principles**

Human rhinovirus is the most common cause of the common cold. Infections peak in the fall and spring but can occur all year. The infection is spread via infected respiratory secretions and direct contact with infected patients. The virus can remain contagious on surfaces for several hours. Hand-to-face inoculation is likely one of the predominant mechanisms of spread, underscoring the importance of frequent handwashing to decrease transmission.

**Clinical Features**

Symptoms of rhinovirus infection are usually limited to the nose, nasopharynx, and pharynx. The common symptoms that occur are sore throat, nasal congestion, low-grade fever, sneezing, and cough. Less commonly in children, rhinovirus can cause lower respiratory tract infections like pneumonia and tracheobronchitis.

**Differential Diagnosis**

Other viruses that cause respiratory illness, such as coronaviruses, respiratory syncytial virus (RSV), parainfluenza viruses, influenza viruses, adenoviruses, and enteroviruses, can produce clinical syndromes similar to those produced by the rhinoviruses.
Adenovirus
Principles
Adenoviruses are double-stranded DNA viruses that commonly cause upper respiratory tract infections, gastrointestinal symptoms, and conjunctivitis. Infection is spread via respiratory droplets and close contact. The viruses are resilient and can survive outside of the body for up to 2 weeks.

Clinical Features
The most common presentation of adenovirus is as a URI with sore throat, cough, and fever. Gastroenteritis and conjunctivitis are also common manifestations. Other syndromes less frequently caused by adenoviruses include hemorrhagic cystitis, infantile diarrhea, myocarditis, encephalitis, and meningoencephalitis. In infants and immunocompromised patients, particularly hematopoietic stem cell transplant and solid organ transplant patients, adenovirus can cause severe life-threatening illness.

Differential Diagnosis
Other pathogens causing similar atypical pneumonia syndromes include influenza and parainfluenza viruses and Mycoplasma pneumoniae. Diarrheal syndromes may be similar to those caused by rotaviruses.

Diagnostic Testing
Because adenovirus mostly causes a benign self-limiting disease, routine diagnostic testing is unnecessary. If testing is required, qualitative or quantitative PCR from serum, tissue, or body fluid is the most diagnostic method.

Management and Disposition
The majority of these infections require only symptomatic treatment. There is no specific antiviral therapy that is routinely recommended. There have been reports of using cidofovir in immunocompromised patients with life-threatening adenovirus infection, but this is not routinely recommended. The majority of these patients will be treated at home. The most severe cases may require admission.

Parainfluenza
Principles
Parainfluenza is a single-stranded RNA virus that belongs to the Paramyxoviridae family. This infection is usually acquired in childhood. In the United States, parainfluenza infections have been reported to account for up to a quarter of respiratory disease in children. In adults, the burden of illness caused by parainfluenza is much less. There are four types each with their own clinical presentation. Parainfluenza is transmitted by close contact via infected respiratory secretions.

Clinical Features
Parainfluenza type 1 is the most common cause of croup. Parainfluenza type 2 is also associated with croup but causes less morbidity. Croup symptoms usually worsen at night and are characterized by a barking cough. Typically patients will have a fever and URI symptoms 1 to 2 days before the cough. Tachypnea and hoarse voice are common as well. In severe cases, stridor at rest may be present. Parainfluenza type 1 and 2 also cause lower respiratory tract infections in children. Parainfluenza type 3 more often causes bronchitis, bronchiolitis, and pneumonia. Parainfluenza type 4 is less common and causes a mild respiratory illness. In adults and older children, parainfluenza infections are mild and present as a simple URI.

Differential Diagnosis
Adenoviruses, rhinoviruses, influenza viruses, RSV, echoviruses, coxsackieviruses, and coronaviruses all can cause similar URI symptoms. If the primary presentation is croup, it is important to consider epiglottitis as a potential diagnosis.

Diagnostic Testing
Diagnosis is made from viral culture, rapid antigen test, or PCR. Specimens are usually obtained from nasal or throat swabs, or nasopharyngeal washings.

Management
There is no specific antiviral treatment for parainfluenza infection. The treatment is mainly symptomatic. For mild and moderate croup, a single dose of oral dexamethasone (0.6 mg/kg, maximum dose 20 mg) can be given.38 For severe croup, nebulized racemic epinephrine should be administered in addition to oral or intramuscular corticosteroids.

Disposition
Most parainfluenza infections can be treated as an outpatient. Patients with mild croup can be discharged home. Patients with moderate and severe croup should be observed in the ED to ensure improvement before discharged home. If no improvement occurs after 4 hours, admission should be considered. Patients who receive racemic epinephrine should be monitored for at least 2 hours to ensure their severe symptoms do not recur. If they are well appearing, they can be discharged home. Patients that have continued stridor at rest, moderate to severe chest retractions, or hypoxemia should be admitted to the hospital.

Respiratory Syncytial Virus
Principles
RSV is an RNA virus that belongs to the Paramyxoviridae family. RSV causes significant morbidity in children. It is an important cause of death in young children in the developing world. In the United States, RSV is associated with approximately 20% of hospitalizations and 18% of ED visits in children younger than 5 years old. RSV is also an important cause of respiratory illness in the elders, affecting 3% to 10% of the population older than age 65 each year. RSV is spread via contact with
RSV causes a range of respiratory disease. The illness is most severe in infants, causing pneumonia and bronchiolitis. Newborns with RSV can present with apnea. Symptoms usually begin with nasal congestion, rhinorrhea, low grade fever, and cough. Then 1 to 2 days after symptom onset, patients develop wheezing and increased respiratory effort. Symptoms can last up to 2 weeks. In adults and older children, RSV usually causes a benign URI typically lasting less than 5 days. Elders, immunosuppressed patients, and adults with chronic medical problems can develop severe lower respiratory tract disease.

**Differential Diagnosis**

The clinical presentation caused by RSV infections is similar to other upper and lower respiratory tract pathogens, including rhinovirus, parainfluenza, influenza, enteroviruses, coronaviruses, and bacterial causes of pneumonia. It is important to consider noninfectious causes of hypoxemia in infants, such as foreign body aspiration and asthma.

**Diagnostic Testing**

The common methods of diagnosis include viral culture, PCR, and rapid antigen detection tests. Specimens are typically obtained from nasopharyngeal swabs or washings. Other routine diagnostic testing is generally unnecessary and should be symptom targeted.

**Management**

The mainstay of treatment is supportive care. Beta-agonist bronchodilators are not recommended by the most recent guidelines published by the AAP. We agree that routine inhaled bronchodilators should not be used for RSV bronchiolitis given the lack of evidence of improved outcomes. However, it is reasonable to administer a trial of inhaled albuterol for severe disease, because most of these patients were excluded from studies and some of the patients may actually have viral-induced asthma exacerbation. Corticosteroids have not been shown to provide any benefit. Supplemental oxygen should be provided for pulse oximetry less than 90%. Nebulized hypertonic saline can be used as an inpatient, currently data do not support use in the ED. For severe cases nasal continuous positive airway pressure (CPAP) can be trialed to avoid intubation. It is also important to treat dehydration associated with the disease with IV or nasogastric fluids if the patient cannot maintain oral intake. For prevention of RSV infection in high risk patients, the AAP recommends the use of palivizumab, a monoclonal anti-RSV antibody preparation, during the first year of life for infants with hemodynamically significant heart disease or chronic lung disease of prematurity defined as preterm infants younger than 32 weeks gestation who require more than 21% oxygen for at least the first 28 days of life.

**Disposition**

Healthy adults and older children have a short disease course that is mild and can be treated at home. The majority of infants with the RSV will also be treated at home but may have prolonged illness. Infants younger than 1 year old that visit the ED for bronchiolitis have a median duration of symptoms of 15 days, and over a third of them have a subsequent unscheduled medical visit. Approximately 1% to 3% of infants with RSV will require hospitalization for hypoxemia, respiratory distress, or dehydration. Approximately 15% of elders hospitalized with an acute cardiopulmonary diagnosis are diagnosed with RSV infection requiring ICU care.

**VIRUSES ASSOCIATED WITH DIARRHEAL ILLNESS**

**Norovirus and Rotavirus**

**Principles**

Norovirus is a member of the Caliciviridae family and is the most common cause of nonbacterial gastroenteritis. The infection is highly infectious because only a few particles are necessary to transmit the disease. Norovirus is spread through direct transmission from person to person via the fecal-oral route. Transmission can also occur through contaminated water, food, and surfaces. Norovirus is very stable in the environment and is resistant to most disinfectants, including alcohol hand wash. Outbreaks of norovirus occur in areas where people are in close proximity, including long-term care facilities, restaurants, hospitals, schools, and cruise ships. The number of ED visits for norovirus peaks in the winter months.

Rotaviruses are double-stranded RNA viruses that belong to the Reoviridae family. These viruses are present all over the world, and by 5 years old most children have been exposed to them. They are the leading cause of severe gastroenteritis in children. Since the introduction of rotavirus vaccine in developed countries, medical encounters for this disease have drastically decreased.

**Clinical Features**

**Norovirus.** The disease causes a severe gastroenteritis, with vomiting, diarrhea, and abdominal cramping. In infants and children, vomiting is the primary symptom, whereas adults more commonly have diarrhea. The gastrointestinal symptoms can be accompanied by fever, headache, and myalgias as well. The diarrhea is typically non-blood, watery, and profuse. The acute illness usually lasts for \( \frac{3}{4} \) to 3 days.

**Rotavirus.** The illness manifests as sudden onset of nausea, vomiting, and profuse watery diarrhea, with fever, headache, and myalgias. The disease course is usually 3 to 7 days. The spectrum of disease can range from asymptomatic to severe fatal dehydration.

**Differential Diagnosis**

Other causes of viral gastroenteritis include adenovirus, enterovirus, and certain coronaviruses. *Clostridium difficile* infection and some bacterial gastroenteritis can present similarly as well.

**Diagnostic Testing**

Norovirus diagnosis can be confirmed by PCR of stool or vomit specimen. Rapid antigen detection test of stool specimen. The disease course is typically short, and recovery is prompt.

**Management**

There is no specific treatment for these viral gastrointestinal infections. Management centers on ensuring that patients are adequately hydrated and correcting significant electrolyte derangements. Most patients can be treated with oral rehydration alone. Patients with severe dehydration warrant IV rehydration. Meticulous attention to standard precautions and hand hygiene is important to prevent spread of these diseases.
Disposition
The majority of patients can be managed at home with oral therapy. Very young patients or patients with chronic illness may be at risk for more severe disease and benefit from IV therapy and monitoring. Depending on the severity of illness, these patients could be managed in an observation unit or may require inpatient admission.

**VIRAL INFECTIONS WITH NEUROLOGIC MANIFESTATIONS**

**Principles**
Arboviruses are a group of viruses that are transmitted via arthropod vectors, generally mosquitoes and ticks. Encephalitis is a common manifestation of arboviral infection. Most of these viruses are primarily transmitted from the arthropod vector to another animal, and humans are only incidentally infected. The arboviral viruses that cause encephalitides belong to the following families: *Flaviviridae*, *Togaviridae*, *Bunyaviridae*, and *Reoviridae*.

- St. Louis encephalitis virus, West Nile virus (WNV), and Japanese encephalitis virus belong to the *Flaviviridae* family. These viruses are primarily maintained in a natural cycle of bird-mosquito-bird transmission. Given the mosquito vector, in North America and other temperate climates, these infections have a higher incidence in the summer months. WNV was popularized at the turn of the 20th century because of its first time appearance in the western hemisphere. WNV was originally localized to Africa and the Middle East, but in 1999 WNV emerged in New York City and since then has spread to the Pacific coast, as far south as Argentina, and as far north as Canada. Now WNV is the leading cause of domestically acquired arboviral infection in the United States. In Asia, Japanese encephalitis virus is the most prevalent cause of viral encephalitis with the greatest morbidity as well.

- La Crosse virus and California encephalitis virus belong to the *Bunyaviridae* family. According to data from the state health departments, La Crosse virus was the most common cause of encephalitis among children in the United States from the years 2003 to 2012. Eastern equine encephalitis (EEE) virus, Western equine encephalitis virus, and Venezuelan equine encephalitis virus belong to the *Togaviridae* family and cause infections in certain parts of North and South America.

**Clinical Features**
Arboviral infections cause a wide range of presentation including subclinical disease, nonspecific febrile illness, hemorrhagic fever, meningitis, acute flaccid paralysis, and severe encephalitis. Typically encephalitis patients will begin with a nonspecific febrile illness accompanied by malaise, sore throat, and respiratory symptoms. Headache, photophobia, meningismus, lethargy, somnolence and altered mental status will then follow. Severe disease can manifest as paralysis, coma, and seizures. Depending on the virus, it can be common for patients that recover to have some neurologic sequelae.

**West Nile Virus**
The majority of people who become infected with WNV are asymptomatic. The most common presentation of symptomatic WNV is West Nile fever, a self-limiting illness characterized by fever, headache, malaise, and myalgias. Patients can also experience gastrointestinal symptoms as well. Between a quarter to half of the patients can also have an accompanying maculopapular rash on the chest, back, and arms. It is estimated that around 1% of WNV causes neuroinvasive disease. The neuroinvasive disease manifests as meningitis, encephalitis, or a flaccid paralysis. WNV neuroinvasive disease carries with it a 10% mortality rate. Age and organ transplantation have been identified as a risk factor for more severe neuroinvasive disease and mortality for WNV infections.

**Eastern Equine Encephalitis Virus**
EEE virus is the most dangerous of the viruses that cause encephalitides. It occurs along the Gulf and Atlantic coast with predominance in the late summer months. The usual manifestation is fever, chills, headache, and myalgias lasting 1 to 2 weeks, typically followed by resolution. A small portion of patients will go on to develop encephalitis with headache, nausea, vomiting, altered mental status, and focal neurologic deficits. Approximately 2% to 6% of infected patients develop rapidly deteriorating severe encephalitis that results in coma. EEE virus infection that results in encephalitis is associated with 30% mortality.

**St. Louis Encephalitis Virus**
The majority of infections are asymptomatic, but as patients get older the rate of symptomatic infections increases dramatically. The incubation period varies from 4 to 21 days. Symptomatic disease presents as fever, myalgias, and headaches. Patients older than 60 frequently present with encephalitis, with mental status ranging from lethargy to coma. Acute flaccid paralysis occurs in approximately 6% of patients with encephalitis.

**Differential Diagnosis**
The diagnosis of arboviral encephalitis is difficult based on clinical presentation alone. It shares many features with other arboviral infections, other viral causes of encephalitis, bacterial meningitis, HSV encephalitis, leptospirosis, Lyme disease, and brain abscess.

**Diagnostic Testing**
The primary method of diagnosis is CSF analysis for serologic markers or PCR. WNV encephalitis is diagnosed by detecting IgM antibody in CSF. Viral culture is not commonly used for these diagnoses. There is often a broad differential diagnosis when evaluating these patients, so it is very important to elicit travel and potential exposure history to narrow the differential diagnosis. When performing a LP, it can be helpful to obtain an extra tube or vial of CSF to put on hold. This extra CSF sample is useful because testing for arboviral infections is often sent after the initial evaluation, assessing for more common etiologies of neurologic infection, such as bacterial meningitis or HSV encephalitis, is completed. CSF will demonstrate an elevated WBC count, with lymphocyte predominance. Early during a WNV infection there may be a neutrophil predominance. Ancillary testing with CT or MRI may be indicated, depending on the severity of neurologic symptoms.

**Management**
The treatment for these entities remains largely symptomatic. There is no specific antiviral therapy or immunoglobulin treatment with proven benefit. In patients that develop cerebral edema, the therapies focus on preventing secondary brain injury and treatment of cerebral edema by maintaining adequate cerebral perfusion pressure, treating seizures, and avoiding hypoxemia, high fever, and hypoglycemia or hyperglycemia.
Patients with neurologic symptoms should be admitted to the hospital. These patients often require neurology and infectious disease specialists to consult in their care. Arboviral infections are reportable diseases. Long-term outcomes for these patients can vary. Full recovery can usually be expected in patients with WNV meningitis. WNV encephalitis patients often have residual effects, with over half of them reporting some type of persistent symptoms (fatigue, muscle aches, decreased activity, memory difficulty, concentration difficulty) beyond 6 months.

**VIRAL HEMORRHAGIC FEVERS**

**Dengue Virus**

**Principles**

Viruses in the *Flaviviridae* family can also cause hemorrhagic fevers. Dengue is the most common virus in this family to cause human infection. It can be found all over the world, with most infections occurring in Southeast Asia, the Western Pacific, and Central and South America. It is one of the most important causes of fever in the returned traveler. It is transmitted via the mosquito vector, *Aedes aegypti* and *Aedes albopictus*, and humans are the natural host.

**Clinical Features**

Dengue can cause a wide spectrum of disease. Many infected individuals with dengue are asymptomatic. Dengue fever is a self-limited illness characterized by fever, headache, retroorbital pain, severe myalgias, and arthralgias. Symptoms can last up to 1 week. Dengue hemorrhagic fever (DHF), a more severe syndrome, occurs when the following four criteria are present: (1) increased vascular permeability (pleural effusion, ascites, hemoconcentration), (2) thrombocytopenia, (3) fever lasting 2 to 7 days, and (4) hemorrhagic tendency or spontaneous bleeding. Dengue shock syndrome (DSS), the most severe presentation of dengue infection, is present when DHF occurs with circulatory shock.

**Differential Diagnosis**

Other diagnoses to consider in suspected dengue patients include malaria, chikungunya, rickettsial infections, leptospirosis, and other viral hemorrhagic fevers, including Ebola, Marburg, yellow fever, or bunyaviruses. It is also important to consider the diagnosis of measles in a returned febrile traveler with a rash, because many countries that have endemic dengue also have endemic measles.

**Diagnostic Testing**

The diagnosis can be made via serologic testing with IgM assay or viral RNA detection with RT-PCR. Other laboratory findings that may be present with dengue infection include leukopenia, thrombocytopenia, elevated hematocrit (due to hemoconcentration from fluid loss), and abnormal liver function tests. In DHF, coagulopathy can be present.

**Management**

There are no specific antiviral agents that treat dengue. The treatment is mainly supportive. Dengue fever is usually a self-limited illness and can be treated with rest, antipyretics, analgesics, and fluid replacement therapy. Nonsteroidal anti-inflammatory drugs and aspirin should be avoided given the bleeding tendencies associated with these medications. Patients with DHF and DSS require close monitoring, IV fluid replacement therapy, and organ support as indicated. Hemorrhagic sequelae are treated with blood product transfusions as needed. Steroid therapy for severe dengue has been evaluated in several low quality studies, but the evidence to date is inconclusive and steroid treatment cannot be recommended at this time. The control of epidemics revolves around reducing the mosquito vector population and preventing humans from being bitten by mosquitoes.

**Disposition**

Depending on the severity of illness, patients with dengue fever can be treated as an outpatient; some may require admission for rehydration therapy. Patients with DHF will require admission to the hospital for monitoring and IV fluid resuscitation and patients with DSS will require admission to the ICU.

**Chikungunya Virus**

**Principles**

Chikungunya is an arbovirus in the *Alphaviridae* family that was originally endemic to West Africa. Since early this millennium, the infection has spread broadly, responsible for multiple outbreaks in Asia, Europe, and the Indian subcontinent. In 2013, local transmission was identified in the Americas for the first time. The vectors are the same as dengue, the *Aedes aegypti* and *Aedes albopictus* mosquitoes.

**Clinical Features**

Chikungunya causes a self-limiting disease very similar to dengue. Fever, myalgias, and polyarthralgias are the hallmark of this disease. The joint pain can be so severe that ambulation is impaired. Symptoms typically last for 7 to 10 days. More than half of infected individuals will develop a maculopapular rash several days after fever onset. Risk factors for severe disease with a higher mortality include age older than 65 years old, diabetes, and underlying cardiopulmonary disorders.

**Differential Diagnosis**

Other febrile illnesses with rash and myalgias, and arthralgias should be considered, including dengue, malaria, African tick bite fever, leptospirosis, measles, rubella, relapsing fever, EBV, and meningococcal disease. Noninfectious disorders such as adult onset Still’s disease and other rheumatologic disorders should also be considered.

**Diagnostic Testing**

The diagnosis can be confirmed via enzyme-linked immunosorbent assay (ELISA) testing for antibodies, RT-PCR for detecting viral RNA, or viral culture. Lab abnormalities that may be associated with acute infection include abnormal liver function tests, thrombocytopenia, and lymphopenia.

**Management and Disposition**

Treatment is mainly supportive. Antipyretics, anti-inflammatory agents, and analgesics play an important role in symptom control. IV fluids may be necessary, depending on disease severity. Prevention of disease centers on reducing mosquito exposure. Most patients can be treated at home. Patients that present with severe disease may require admission IV hydration and observation until they are stable.
Yellow Fever Virus

Principles

Yellow fever virus is another arbovirus in the *Flaviviridae* family that can cause a viral hemorrhagic fever. Prior to the discovery of its mosquito vector transmission, there were multiple yellow fever epidemics in Africa, Europe, and the Americas. The vector is the *Aedes* or *Haemagogus* mosquito. Vector control and development of a vaccine have greatly reduced the burden of this disease over the past several decades. Currently yellow fever occurs in tropical regions of Africa and South America.

Clinical Features

The incubation period is between 3 to 6 days. Patients present with an acute febrile illness accompanied by chills, malaise, headache, myalgias, nausea, and dizziness. Patients can have a much lower heart rate than expected in reference to the high fever that is present. This acute febrile phase of the illness can last between 3 to 6 days. Patients then experience a short period of remission, lasting up to 24 hours; some patients recover completely, whereas others go on to have a more severe recurrence of illness with fever, vomiting, jaundice, acute liver injury, acute renal failure, and hemorrhagic manifestations. The hallmark feature of yellow fever is jaundice with hemorrhagic fever. The mortality of patients with hepatorenal involvement ranges from 20% to 50%.

Differential Diagnosis

One must consider other febrile illnesses that occur in these endemic areas, including leptospirosis, relapsing fever, viral hepatitis, malaria, other viral hemorrhagic fevers, and dengue.

Diagnostic Testing

Laboratory diagnosis is usually made by detecting IgM and neutralizing antibodies in the serum. There are a number of laboratory abnormalities that occur in this illness, including elevated aspartate transaminase (AST), alanine transaminase (ALT), and direct bilirubin. Patients with severe disease also have hematologic labs consistent with disseminated intravascular coagulation (DIC).

Management

There are no specific antiviral treatments for yellow fever. The treatment is supportive. Fluids, antipyretics, and analgesia are the main symptomatic treatments. Given the risk of hemorrhagic fever, aspirin and nonsteroidal anti-inflammatory drugs should generally be avoided. If severe disease with shock develops, then patients may require IV fluid resuscitation, blood product resuscitation, vasopressors, mechanical ventilation, and renal replacement therapy.

Since there is no specific treatment for yellow fever, much attention has been placed on prevention. Personal protection measures to avoid mosquito bites and vector control at the community level are important in preventing disease. A live-virus vaccine is available for persons travelling to endemic areas. The vaccine is recommended for individuals 9 months old and older who live in or are travelling to endemic areas. Many countries where yellow fever is endemic require a certificate of vaccination for entry.

Disposition

Depending on the severity of illness, patients can be treated at home or may require admission to the hospital. Severe illness may require ICU admission given the high mortality associated with it.

Ebola

Principles

Ebola virus is an RNA virus that belongs to the *Filoviridae* family. Ebola virus disease (EVD) causes a severe viral hemorrhagic fever. Ebola was first described in 1976 in Sudan and what is now the Democratic Republic of the Congo (Zaire at that time). Since then, there have been a number of outbreaks occurring in rural areas in Africa. The current 2014 Ebola outbreak in West Africa is the most severe outbreak in history. It began March 2014 in Guinea and then spread to Sierra Leone and Liberia. Nigeria, Senegal, and Mali have also been affected but to a much lesser degree. As of April 1, 2015, this outbreak has affected 25,228 people and claimed 10,462 lives.50 Prior to this outbreak, the largest recorded outbreak had resulted in fewer than 300 deaths. This outbreak has also resulted in the first cases of Ebola acquired outside of Africa. A female nurse assistant in Spain acquired the disease after caring for an Ebola patient who was transported from Sierra Leone to Spain.51 Subsequently two nurses contracted Ebola in the United States after caring for an Ebola patient who contracted the virus in Liberia.

The mortality rate for Ebola infections ranges from 25% to 90%. Transmission of the virus occurs by direct contact of infected tissue or infected bodily fluids, including blood, saliva, vomit, feces, or semen. Individuals are not contagious until they show symptoms. The usual incubation time is 5 to 7 days but can range from 2 to 21 days.

Clinical Features

The initial symptoms include high fever, headache, myalgias, malaise, sore throat, and profuse vomiting and diarrhea. After 5 to 7 days, patients can progress to develop the hemorrhagic manifestations, which include spontaneous bleeding, ecchymosis, and petechia. It is also common for patients to not develop any hemorrhagic complications.52-53 An erythematous maculopapular rash can occur during that time that eventually desquamates. Patients can become hypovolemic and develop severe metabolic derangements secondary to fluid losses via the gastrointestinal tract. Eventually patients advance to shock and multiorgan failure.

Differential Diagnosis

The symptoms of Ebola are initially nonspecific and overlap with other diseases. Other more common infections from the endemic regions include malaria, typhoid fever, other viral hemorrhagic fevers (ie, Marburg, bunyaviruses), meningococcemia, leptospirosis, or other bacterial illnesses.

Diagnostic Testing

Testing should only be conducted for patients that meet clinical criteria of having exposure history and signs or symptoms of EVD. The hospital should also have a protocol for handling lab specimens of potential EVD patients. The risk of acquiring EVD through lab testing is low but not zero. RT-PCR assay using a plasma specimen is currently the main method of Ebola diagnosis. The turnaround time for this testing can vary from 12 to 24 hours. Recently a rapid antigen point-of-care test, with a turnaround time of 15 minutes has been developed with good sensitivity and specificity as compared to RT-PCR.54 Laboratory findings that can accompany Ebola infection include thrombocytopenia, anemia, coagulopathy, transaminitis, elevated creatinine, hypocalcemia,
and hypokalemia. All patients should have testing for malaria performed with thin and thick smear of the blood. Malaria is much more likely than Ebola in the endemic population and returned travelers. Coinfection is also common; in one study of Ebola patients in Guinea, 11% of the patients had concomitant malaria infection.\(^5\)

**Management**

The important guiding principles when managing a suspected EVD case are to treat the patient and prevent the spread of the infection. The CDC has developed practical algorithms for evaluating suspected EVD cases in United States EDs ([www.cdc.gov/vhf/ebola/pdf/ed-algorithm-management-patients-possible-ebola.pdf](http://www.cdc.gov/vhf/ebola/pdf/ed-algorithm-management-patients-possible-ebola.pdf)). The basic tenets are to identify, isolate, and inform (Box 122.2).

The main therapy for Ebola victims is supportive care. Patients are empirically managed with malaria treatment, broad spectrum antibiotics, and antipyretics. They also require rehydration therapy, preferably with IV fluid and electrolyte repletion. Additionally, many EVD patients will require support of organ failure. This may necessitate renal replacement therapy, mechanical ventilation, vasopressors, or blood product administration.

There are a number of experimental therapies currently being tested for EVD. Two United States health care workers that contracted Ebola in Liberia and were treated in the United States tested for EVD. Two United States health care workers that contracted Ebola in Liberia and were treated in the United States received an investigational therapy called ZMapp under emergency investigational new drug approvals from the FDA.\(^5\)

ZMapp is a combination of three humanized mouse monoclonal antibodies against Ebola viral antigens. The WHO also approved the use of convalescent serum from Ebola patients to treat acute EVD patients.\(^5\)

**Disposition**

It is paramount that providers caring for potential EVD patients be familiar with proper isolation practices. The CDC stresses that health care providers should receive extensive training and demonstrate competency in Ebola-related infection control procedures specifically in putting on and removing the PPE. Many hospitals have developed internal guidelines, but the CDC website is a useful resource and gives comprehensive guidance regarding how to deal with potential EVD patients in the United States health care setting ([www.cdc.gov/vhf/ebola/healthcare-us/index.html](http://www.cdc.gov/vhf/ebola/healthcare-us/index.html)).

The CDC has also developed a strategy to help hospitals prepare for suspected EVD cases ([www.cdc.gov/vhf/ebola/pdf/preparing-hospitals-ebola.pdf](http://www.cdc.gov/vhf/ebola/pdf/preparing-hospitals-ebola.pdf)). There is a tiered system categorized by frontline health care facilities, Ebola assessments hospitals, and then Ebola treatment centers. All hospitals should have and follow infection control protocols, ensure staff is trained and competent in safe PPE practices, and have a system in place to manage waste disposal, cleaning, and disinfection. Patients with suspected EVD are admitted to hospital isolation rooms, and many of them will need ICU care. As previously stated, the mortality of EBV is high, but with access to modern medical facilities with ICUs, patients are likely to have much better outcomes than previously reported.

---

**BOX 122.2**

**Centers for Disease Control and Prevention Algorithm for Emergency Department Identification of Ebola Virus Disease**

1. **Identify:** Emergency department (ED) providers should identify patients at risk for Ebola virus disease (EVD) by identifying exposure history and then determining if signs and symptoms of EVD are present. **Exposure history:**
   - Has the patient lived in or travelled to a country with Ebola?
   - Has the patient had contact with an individual with confirmed EVD in the past 21 days?

**Identify signs and symptoms:**
   - Fever (subjective or \(\geq 100.4^\circ\) F or \(38.0^\circ\) C)
   - Headache
   - Weakness
   - Myalgias
   - Vomiting
   - Diarrhea
   - Abdominal pain
   - Hemorrhage

2. **Isolate:** Once a patient has been screened positive as a potential EVD patient (has both exposure history and signs or symptoms compatible with EVD), he or she should be isolated immediately to a private room that can be closed, with a private bathroom or covered bedside commode. The staff caring for this patient needs to wear appropriate personal protective equipment (PPE) and a log should be kept of everyone entering and leaving the room.

3. **Inform:** Hospital infection control and the health department should be immediately notified. To protect health care providers and prevent the spread of Ebola, ED providers should be familiar with these procedures for potential EVD patients.

---

**Marburg**

**Principles**

Marburg virus is an RNA virus that belongs to the Filoviridae family. It is an important cause of viral hemorrhagic fever in central Africa. Marburg cases have occurred in the following countries: Uganda, Zimbabwe, the Democratic Republic of the Congo, Kenya, and Angola. Cases have been reported outside Africa, including Germany, the former Yugoslavia, Netherlands, and the United States, all with confirmed exposure to an African source. The virus was described first in 1967 after an outbreak occurred in Marburg, Germany, when laboratory personnel working with African Green monkeys developed fever and hemorrhagic shock. Direct transmission occurs with contact with blood, secretions, or solid organs of infected individuals. It is currently thought that the natural host of the Marburg virus is the African fruit bat. The incubation period is 3 to 9 days. The disease carries a similar fatality rate to Ebola, with case fatality rate ranging from 24% to 88%.

**Clinical Features**

Marburg and Ebola virus cause a very similar clinical syndrome. Marburg virus illness initially causes fever, headache, malaise, and myalgias. After the 3rd to 5th day, severe abdominal pain, cramping, vomiting, and diarrhea occurs. Around the same time, a maculopapular rash may develop. Half of the patients will also develop hemorrhagic manifestations during this time. Hematemesis, diarrhea, oropharyngeal bleeding, and bleeding from venipuncture sites can all occur. Death usually occurs because of acute blood loss and septic shock.

**Differential Diagnosis**

The differential diagnosis of Marburg infection is very similar to that of Ebola infection in that the symptoms are initially
nonspecific and overlap with other diseases. Other more common infections from the endemic regions include malaria, typhoid fever, other viral hemorrhagic fevers (ie, Marburg, bunyaviruses), meningococcemia, leptospirosis, or other bacterial illnesses.

**Diagnostic Testing**

Diagnosis requires laboratory testing, because the clinical features overlap with many other viral hemorrhagic fevers. Diagnosis can be made via RT-PCR, ELISA, antigen detection tests, serum neutralization tests, and viral culture.

**Management**

The priorities of managing a suspected Marburg hemorrhagic fever (MHF) case are similar to a suspected EVD case. Early recognition is key for controlling the spread of this infection. It is important to consider this disease in potential patients by assessing the patient for travel history to countries with endemic MHF or contact with someone who has had MHF within the past 3 weeks and then assessing if symptoms consistent with MHF are present. Patients identified at risk by the screening process should be isolated to a private room with private bathroom. Public health authorities and hospital infection control personnel should be immediately informed. Please refer to the Ebola section of this chapter for further details.

There is no specific treatment for MHF. The treatment is mainly supportive and directed at the patient’s symptoms. Patients will initially require large fluid volume resuscitation and antipyretics. Patients that develop end-organ failure will require advanced therapies, such as vasopressors, mechanical ventilation, and renal replacement therapy. Patients with hemorrhagic manifestations will also require blood product resuscitation with packed red blood cells (PRBCs) and fresh frozen plasma.

**Disposition**

Patients with MHF will require admission to the hospital and many will require ICU admission. It is important to observe strict isolation practices and ensure that staff use PPE when caring for the patient. When appropriate, patients should be transferred to specialized treatment centers that are prepared and designated to care for patients with viral hemorrhagic fevers.

**Lassa Fever**

**Principles**

Lassa virus is an *Arenavirus* that is endemic to West Africa. Its reservoir is an African rodent *Mastomys natalensis*. Humans contract the disease by exposure to urine or feces of *Mastomys natalensis*. Human to human transmission can occur via contact with blood or bodily secretions from infected humans. The incubation period is usually around 10 days, but can range from 3 to 21 days. Unlike Ebola and Marburg, the majority of Lassa infections are asymptomatic. The case fatality rate is less than 2%.

**Clinical Features**

When patients are symptomatic with Lassa fever, symptoms usually begin with gradual onset of fever and malaise. Headache, myalgia, sore throat, cough, chest pain, abdominal pain, nausea, vomiting, diarrhea can all occur after a few days. Patients can also develop facial edema, pleural effusion, myocarditis, and encephalitis. Less than 20% of symptomatic patients progress to develop hemorrhagic manifestations. Patients that do go on to have full-blown hemorrhagic fever have a much higher mortality rate. Third trimester pregnancy is associated with a more severe disease with high mortality as well.

**Differential Diagnosis**

The differential diagnosis is broad and includes that of other viral hemorrhagic fevers.

**Diagnostic Testing**

Diagnosis on clinical grounds alone is difficult, because Lassa fever shares features with many other diseases. Diagnosis can be made via RT-PCR, ELISA, antigen detection tests, and viral culture.

**Management**

Ribavirin has been shown to decrease overall mortality. The greatest effect occurs when treatment is initiated early within the first 6 days after fever onset. The remainder of treatment is supportive care with volume resuscitation, antipyretics, and blood product administration if hemorrhagic disease occurs. As with other viral hemorrhagic fever support of organ failure with mechanical ventilation, vasopressors, and renal replacement therapy may also be needed. Although high quality evidence does not exist, guidelines do recommend ribavirin as postexposure prophylaxis for definitive high-risk exposures. Prevention of Lassa fever at the community level centers on good hygiene and rodent control.

**Disposition**

Symptomatic patients with Lassa fever will require hospital admission. The same principles of the other viral hemorrhagic fevers of prompt recognition, identification, isolation, and informing authorities apply to Lassa fever as well. Please refer to the prior sections in this chapter on Ebola and Marburg for more details.
There have been recent outbreaks of vaccine-preventable childhood infections secondary to unvaccinated individuals and travel to areas where disease is still endemic. Emergency clinicians should recognize the possibility of these once rare diseases.

Herpes simplex encephalitis is a severe disease that is fatal if left untreated. Clinicians should suspect this diagnosis when evaluating severely ill patients for suspected meningitis or encephalitis, and promptly institute empirical therapy with IV acyclovir while awaiting diagnostic results.

Primary varicella can be dangerous in select populations, including older children, adults, and pregnant patients. These patients require treatment with acyclovir.

Zoster patients should be treated with acyclovir if they present within 72 hours of symptoms onset or if they are immunocompromised regardless of duration of illness. Disseminated zoster should be treated with IV acyclovir.

In generally healthy patients with influenza infection, the duration of illness can be shortened by almost 1 day if antiviral treatment is administered within 48 hours of symptom onset. Hospitalized patients with influenza infection should be treated with antiviral medication regardless of duration of symptoms, because it may decrease mortality and influenza complications.

There are many emerging viral infections including SARS-CoV, MERS-CoV, and Ebola that should be considered in febrile patients. It is important to identify patients at risk by determining travel history and exposure history to individuals with confirmed infection. Once a patient is deemed at risk, the patient should be promptly isolated according to established guidelines while further investigation occurs. It is also important to immediately inform the hospital infection control program and public health agencies.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
122.1. Which of the following patients does not require antiviral treatment for confirmed influenza infection?

A. 1-year-old male with 24 hours of symptoms.
B. 22-year-old otherwise healthy female with symptoms for 3 days.
C. 71-year-old male with a history of asthma and morbid obesity with symptoms for 2 days.
D. 15-year-old male with no significant past medical history with symptoms for 5 days, intubated with severe hypoxemic respiratory failure, admitted to the intensive care unit (ICU).
E. 65-year-old male with history of asthma, coronary artery disease, congestive heart failure with 2 days of mild symptoms.

Answer: B. The 22-year-old female with no risk factors for influenza related complications does not require antiviral treatment since her symptoms have been present for 4 days. The Centers for Disease Control and Prevention (CDC) recommends treating all patients as early as possible who are hospitalized, have severe illness, or are at risk for influenza related complications. The greatest efficacy for antiviral treatment is within 48 hours of symptom onset, but admitted patients with severe disease should be treated regardless of symptom onset.

122.2 A 19-year-old female presents to the emergency department (ED) with fever, altered mental status, and seizures. She is a college student and lives in a dormitory. Her only past medical history is occasional cold sores. She had been in her usual state of health until 2 days ago when she developed fevers up to 38.5°C and headache. Today she became more lethargic and had two generalized seizures prior to ED arrival. What is the next best course of action?

A. Administer 2 g intravenous (IV) ceftriaxone, 1 g IV vancomycin, IV acyclovir 10 mg/kg every 8 hours, order computed tomography (CT) scan of head, and then perform lumbar puncture (LP).
B. Administer 2 g IV ceftriaxone and admit to internal medicine service for further evaluation.
C. Administer 650 mg acetaminophen, 2 liters of IV fluids, and admit to the observation unit with the diagnosis of viral syndrome.
D. Order magnetic resonance imaging (MRI) of the brain, administer 1 g phenytoin, and consult neurology.
E. Prescribe 1 g valacyclovir twice daily for 10 days and 650 mg acetaminophen every 4 to 6 hours as needed and discharge home.

Answer: A. This patient has herpes simplex virus (HSV) encephalitis. Given the high mortality associated with this condition, antiviral therapy should be started as soon as the diagnosis is suspected. There is significant overlap in the clinical presentation of bacterial meningitis and HSV encephalitis, so patients should empirically be treated for both diagnoses while awaiting cerebrospinal fluid (CSF) results. HSV encephalitis cannot be treated as an outpatient and requires 14 to 21 days of treatment with IV acyclovir. An MRI may be necessary eventually to look for temporal lobe involvement but is not necessary at the time of ED presentation and can be negative early in the course of disease.

122.3. Which of the following associations is correct?
A. Chikungunya virus—viral hemorrhagic fever
B. Ebola virus—febrile illness with severe arthralgias and myalgias
C. Herpes simplex virus type 1 (HSV-1)—benign meningitis
D. Herpes simplex virus type 2 (HSV-2)—necrotizing hemorrhagic encephalitis
E. Middle East respiratory syndrome coronavirus (MERS-CoV)—severe acute respiratory failure

Answer: E. MERS-CoV causes an acute respiratory illness with fever, cough, and dyspnea. HSV-1 causes necrotizing hemorrhagic encephalitis, typically involving the temporal lobes. HSV-2 can cause meningitis in over 25% of patients with primary infection. In contrast to HSV encephalitis, HSV meningitis has a benign course. Ebola virus causes a severe hemorrhagic fever. Chikungunya causes a self-limiting disease with fever, myalgias, and polyarthralgias.

122.4 An 18-year-old male who arrived from Sierra Leone 2 weeks ago presents with fever, headache, vomiting, and rash. He has a temperature of 103.1°F (39.5°C) and erythematous maculopapular rash over his trunk, back, and arms. He appears ill and severely dehydrated. Which of the following is immediately indicated?
A. 2 g ceftriaxone and lumbar puncture (LP)
B. Intravenous (IV) acyclovir for 10 days
C. Isolation and contact the public health department
D. Ribavirin
E. Thin and thick smear to check for malaria

Answer: C. This is a classic presentation for Ebola virus disease (EVD). The exposure history is important. Patients should be asked if they have lived or travelled to a country with Ebola or had contact with a confirmed EVD patient in the past 21 days. If the answer is yes, then the next task is to assess for any signs or symptoms compatible with Ebola, including fever, headache, weakness, myalgias, vomiting, diarrhea, abdominal pain, or hemorrhage. Once a patient has been screened positive as a potential EVD patient, he or she should be immediately isolated and hospital infection control and the health department should be notified at once.

122.5. Which of the following viruses is not transmitted by a mosquito vector?
A. Chikungunya virus
B. Dengue virus
C. Lassa fever virus
D. West Nile virus (WNV)
E. Yellow fever virus

Answer: C. The reservoir for the Lassa virus is an African rodent Mastomys natalensis. Humans contract the disease by exposure to urine or feces of Mastomys natalensis. Human to human transmission can occur via contact with blood or bodily secretions from infected humans. The other viruses are all arboviruses transmitted via a mosquito vector.
**CHAPTER 123**

Rabies

Jeffrey Bullard-Berent

---

**PRINCIPLES**

Rabies is one of the first infectious diseases described in recorded history, and it remains a huge public health problem, particularly affecting vulnerable populations in poor and rural areas.  

Human rabies disproportionately affects children, with an estimated 40% of rabid bites occurring in those 15 years of age and younger. The World Health Organization (WHO) has estimated approximately 61,000 deaths worldwide from rabies annually, with 95% of these occurring in Asia and Africa (Fig. 123.1). As a result of the successful vaccination of domestic animals started in 1947, human rabies is extremely rare in the United States today, with only two or three cases annually; these are typically caused by domestic transmission from non–dog vectors, organ transplantation, or victims infected in other countries from dog or bat bites who are now in the United States.

**Epidemiology**

All mammals may be infected with rabies, but dogs remain the largest reservoir, the most commonly infected, and the leading vector for human rabies. Dogs are the primary reservoir of rabies in Asia and Africa, but many countries in South America with active vaccination programs have shown tremendous reductions in dog and human rabies cases over the past 25 years. In the United States, Canada, Mexico, South America, western Europe, and Australia, bats are an important reservoir and important source of human rabies. In Europe, Canada, and the Arctic, the fox is the principal carrier; in Puerto Rico, it is the mongoose.

The total number of rabies cases in the United States has remained relatively constant over the past 20 years. Over 90% of cases were caused by exposure to the secretions of raccoons (36%), bats (27%), and foxes (25%: Figs. 123.2 to 123.4; and Table 123.1). Rabies caused by exposure to domestic animals represented only 8% of all cases in the United States in 2013. The most common vectors were cats (56%), dogs (19%), and cattle (18%).

Since 2013, 34 cases of human rabies have been diagnosed in the United States. Most occurred in males and resulted from exposure to dogs, bats, or foxes or from organ transplantation. Transmission of the rabies virus to humans has been documented by bite and scratch from reservoir animals, with bite transmission much higher than scratch. Human to human transmission has been confirmed through transplantation only.

**Pathophysiology**

Rabies is caused by an RNA virus from the genus lyssavirus, in the family Rhabdoviridae (Fig. 123.5). The rabies virus (RABV) is responsible for most human and animal rabies cases worldwide, but other lyssavirus have also been implicated. RABV is found extensively throughout the world in terrestrial carnivores, but non–RABV lyssavirus is rarely encountered in nonflying carnivores.

Bites through the dermis allow the virus to enter tissues and initiate infection. The virus spreads from muscle tissue to the peripheral nervous system via the neuromuscular junction and then travels to the spinal cord and brain. Host cell machinery is usurped, and rapid replication occurs, at which time clinically apparent disease is seen (Fig. 123.6). Host recognition of the virus stimulates an interferon response, but this is antagonized by the virus phosphoprotein. Infection of the brain is followed quickly by peripheral viral dissemination. For the reservoir species, transmission to the salivary glands proceeds through the parasympathetic and sympathetic nervous systems. The associated aggressive behavior and hypersalivation promotes transmission to new hosts.

The unique spread of RABV via direct nerve conduction routes has given rise to circuit-tracing studies that can detect direct monosynaptic inputs. Using glycoprotein (G)-deleted rabies virus (RvdG) as a marker, the retrograde transmission of rabies virus can be followed over distances of micrometers to centimeters. Wild-type rabies virus spreads across multiple synaptic steps at once because the G protein is not only responsible for binding to the host cell, but also mediates budding of the host cell–derived viral particles. RvdG significantly decreases the release of these particles, thus limiting the spread and allowing tracing of the specific viral migration. This technique is also useful in describing central and peripheral nervous system transmission to genetically identified cell types in mouse cell lines, single neurons, and neurons with particular cell surface receptors.

Neither the rabies virus avoidance of peripheral immune surveillance nor its mechanism for causing death are well understood. In the periphery, the virus replicates slowly and may induce immune suppression; both slow replication and immune suppression have been proposed as causes of its insidious presentation. Infection in the central and peripheral nervous systems leads to multiorgan failure. Upregulation of chemokines, cytokines, and interferons has been demonstrated experimentally in the central nervous system (CNS). Upregulation of interferons drives T cells into the CNS, but this influx does not control the infection, which is invariably fatal. The incubation period of rabies normally extends from 20 to 90 days but has been reported from 10 days to 7 years postexposure. Two forms of clinical rabies are described, encephalitic (furious) and paralytic (dumb). The encephalitic form predominates and represents approximately 70% of all human virus rabies presentations. The initial symptoms of rabies infection are vague and may be confused with other flulike illnesses. Presenting symptoms of furious rabies include headache, malaise, pharyngitis, and weakness. These are typically followed by pruritus and paresthesia at the site of inoculation. Early signs of human rabies include fever, tachycardia, and tachypnea, which are commonly found in other illnesses but, unlike other viral infections, the mortality from human rabies infection is almost 100%. To date, only four patients have survived rabies infection.

**Encephalitic Rabies**

This progresses rapidly over days, and the presenting signs and symptoms are supplanted by diffuse neurologic involvement.
The figures in this map show 2010 estimates or ranges of estimates of the numbers of human deaths from rabies transmitted by dogs, as reported in a 2013 World Health Organization report, the WHO Expert Consultation on Rabies. The rabies virus disproportionately affects people in rural areas, particularly children.

**Fig. 123.1.** Distribution of human rabies infections worldwide. (Adapted from World Health Organization: WHO Expert Consultation on Rabies re-evaluates the burden and methods of treatment. Available at www.who.int/neglected_diseases/support_to_rabies_elimination_2013/en.)

The neurologic findings of anxiety, confusion, insomnia, and cerebellar dysfunction are present and are soon replaced by frank delirium, hallucinations, and clinically defining behavioral changes. Hydrophobia, aerophobia, aggressive behavior, and seizures are the feared clinical symptoms most associated with rabies infection, and these portend death. In the final stage of furious rabies, the patient has difficulty swallowing, with involuntary muscles spasms of the pharynx, and hypersalivation occurs. If water is offered, the patient may develop pharyngeal spasm, with resultant gagging. Handling salivary secretions becomes problematic, leading to characteristic drooling and foaming of the mouth. The findings of hydrophobia with resultant gagging and hypersalivation are so characteristic of rabies infection that in many developing countries, water is offered to the patient as a diagnostic test. Coma and death follow rapidly, usually within 5 days of presentation.

Paralytic Rabies

This accounts for approximately 30% of human rabies infections. The presenting symptoms are similar to encephalitic rabies and include headache, weakness, and malaise. Muscle weakness and paresthesia occur at the site of the bite and, over days to weeks, an acute flaccid paralysis ensues. Unlike the encephalitic form, the patient does not develop agitation, hypersalivation, or hydrophobia. Rather, muscle weakness occurs over days to weeks, and the progression to coma and death takes longer than in the encephalitic form. Postexposure prophylaxis (PEP) and rabid bat bites are associated with the paralytic form. Patients are more likely to get rabies from PEP when the recommendations of the WHO and the Advisory Committee on Immunization Practices (ACIP) are not closely followed or rabies immunoglobulin is not given. Patients receiving the nerve cell–derived vaccine that is still used in a few countries are also at greater risk of developing the paralytic form.

**Diagnostic Testing**

Postmortem testing of fresh brain samples remains the gold standard for the diagnosis of rabies in all mammalian species. The WHO and World Organization for Animal Health (OIE) recommend fluorescent antibody testing (FAT) of brain smears or touch impressions. FAT provides reliable results within a few hours that are very sensitive and specific. The best results are obtained with fresh brain tissue, but saline-washed tissue preserved in 30% glycerol saline also works well. Decomposed brain tissue and formalin fixed tissue do not yield results that are as reliable. The limitations of FAT are that it requires brain tissue, expensive fluorescence microscope, and appropriately skilled staff.

If FAT results are equivocal, the OIE recommends virus isolation tests to grow the virus from suspected specimens, which also allows for characterization of the virus. The mouse inoculation test (MIT) and rapid tissue culture infection test (RTCT) can both be used for this purpose. In the MIT, mice are inoculated intracerebrally with supernatant homogenate of brain material. The mice are observed for 28 days and signs of rabies typically develop after 5 to 7 days. The RTCT gives much more rapid results, generally in 24 to 48 hours. Appropriate cell lines are inoculated with brain homogenate, incubated for 24 hours, and stained by the FAT technique. Although RTCT is faster and cheaper than MIT, it requires sophisticated laboratories that have fluorescent microscopes and cell culture facilities.

The direct rapid immunohistochemical test (dRIT) provides results in 1 hour and uses light microscopy rather than expensive fluorescent-labeled antibodies and fluorescent microscopes. The dRIT was developed at the Centers for Disease Control and Prevention (CDC); it has been field-tested in endemic areas and found to be 100% sensitive and specific when compared to FAT. The use of dRIT will allow regions with limited resources to obtain important incidence data, as well as the possibility of carrying out more informed postexposure prophylaxis. However, one significant drawback of dRIT is that the reagents used for the test are only available through the CDC.
PROPHYLAXIS AND VACCINATION

Preexposure Prophylaxis

Pasteur described the first rabies vaccine in 1885. Nerve tissue-derived vaccines similar to Pasteur’s were used worldwide until the 1940s, when they were replaced by cell culture–derived vaccines (CCVs) that were safer and more immunogenic. 

Effective antemortem testing remains elusive. Various forms of molecular methods—reverse transcription (RT) and polymerase chain reaction (PCR) assays—have demonstrated high sensitivity for RABV in dog brain tissue and shown promise for highly sensitive antemortem diagnosis of nuchal skin biopsy, serial saliva, or multiple simultaneous site testing (eg, cerebrospinal fluid [CSF], hair follicles, saliva, urine). Real-time PCR testing of cerebral spinal fluid, nuchal skin, and saliva using the TaqMan probes has demonstrated excellent sensitivity and specificity. Antemortem serologic testing via the use of magnetic resonance imaging may be useful in distinguishing rabies from other forms of encephalitis as typical changes have been described.

Numerous serologic studies have provided evidence of robust production of neutralizing antibody in response to cell culture–derived vaccines. Following the use of WHO-approved vaccines, 100% of healthy individuals were found to have a significant antibody response. No individuals with circulating neutralizing antibody levels above 0.5 IU/mL have ever contracted rabies.

Postexposure Prophylaxis and Vaccination

It has been estimated that 40,000 people receive PEP for rabies in the United States each year. The CDC has reported the cost for treatment at roughly $1000/person, but earlier data suggested an actual cost of $2500 or more. Accordingly, it is imperative that emergency clinicians evaluate each exposure in terms of the regional risk of rabies, animal handling procedures, and indications for PEP. Local or state agencies are familiar with the reservoir populations in that area and serve as a resource. If local public health authorities are unavailable, emergency clinicians evaluate each exposure in terms of the regional risk of rabies, animal handling procedures may call the CDC’s information line, 877-554-4625 or 800-CDC-INFO, 24 hours/day, 7 days/week.

The WHO categorizes exposures in areas enzootic for rabies into three categories. Category I includes touching or feeding animals, licks on intact skin, and contact of intact skin with secretions or excretions of a rabid animal or human. These are not regarded as exposures, and no postexposure prophylaxis is required. Category II includes nibbling of uncovered skin, minor scratches, or abrasions without bleeding. Vaccine should be injected as soon as possible. Category III includes single or multiple transdermal bites or scratches, licks on broken skin, contamination of mucous membrane with saliva from licks, and exposure to intradermal method, and a cost-benefit analysis has suggested that for economic viability, a PrEP regimen that induces immunity with a single injection is needed.

### PROPHYLAXIS AND VACCINATION

Preexposure Prophylaxis

Pasteur described the first rabies vaccine in 1885. Nerve tissue-derived vaccines similar to Pasteur’s were used worldwide until the 1940s, when they were replaced by cell culture–derived vaccines (CCVs) that were safer and more immunogenic. Despite warnings from WHO, some countries still continue to manufacture and use nerve tissue–derived vaccines.

Preexposure vaccine (PrEP) is recommended for travelers to endemic areas and those in high-risk professions (eg, veterinarians, laboratory staff handling the virus). The PrEP regimen recommended by the WHO and ACIP is a three-dose schedule (Table 123.2). Intramuscular or intradermal administration of vaccine is recommended. The intradermal method uses less total vaccine and is thus less expensive in many parts of the world. Approximately 50% of all rabies deaths occur in children younger than 15 years, so preexposure prophylaxis for children in endemic areas should be considered. The current three-dose PrEP regimen is cost-prohibitive in endemic areas, even with the lower cost intradermal method, and a cost-benefit analysis has suggested that for economic viability, a PrEP regimen that induces immunity with a single injection is needed.

Numerous serologic studies have provided evidence of robust production of neutralizing antibody in response to cell culture–derived vaccines. Following the use of WHO-approved vaccines, 100% of healthy individuals were found to have a significant antibody response. No individuals with circulating neutralizing antibody levels above 0.5 IU/mL have ever contracted rabies.

**Postexposure Prophylaxis and Vaccination**

It has been estimated that 40,000 people receive PEP for rabies in the United States each year. The CDC has reported the cost for treatment at roughly $1000/person, but earlier data suggested an actual cost of $2500 or more. Accordingly, it is imperative that emergency clinicians evaluate each exposure in terms of the regional risk of rabies, animal handling procedures, and indications for PEP. Local or state agencies are familiar with the reservoir populations in that area and serve as a resource. If local public health authorities are unavailable, emergency clinicians evaluate each exposure in terms of the regional risk of rabies, animal handling procedures may call the CDC’s information line, 877-554-4625 or 800-CDC-INFO, 24 hours/day, 7 days/week.

The WHO categorizes exposures in areas enzootic for rabies into three categories. Category I includes touching or feeding animals, licks on intact skin, and contact of intact skin with secretions or excretions of a rabid animal or human. These are not regarded as exposures, and no postexposure prophylaxis is required. Category II includes nibbling of uncovered skin, minor scratches, or abrasions without bleeding. Vaccine should be injected as soon as possible. Category III includes single or multiple transdermal bites or scratches, licks on broken skin, contamination of mucous membrane with saliva from licks, and exposure to intradermal method, and a cost-benefit analysis has suggested that for economic viability, a PrEP regimen that induces immunity with a single injection is needed.

Numerous serologic studies have provided evidence of robust production of neutralizing antibody in response to cell culture–derived vaccines. Following the use of WHO-approved vaccines, 100% of healthy individuals were found to have a significant antibody response. No individuals with circulating neutralizing antibody levels above 0.5 IU/mL have ever contracted rabies.
PEP is almost 100% effective when administered according to WHO guidelines. Treatment failures usually occur when local wound care is not complete, immunoglobulin is not given, or nerve cell–derived vaccine is used. Since 1987, only nine PEP treatment failures have been reported in which WHO recommendations were followed and documented.33,34

Once the decision to initiate PEP has been made, it should be started immediately. Currently, four regimens are approved for postexposure treatment of unimmunized individuals, three intramuscular and one intradermal PEP regimens (see Table 123.2). All these regimens include four doses of vaccine following the ACIP recommendations published in 2010.35 The intramuscular dose is 1.0 mL/injection, and the intradermal dose is 0.1 mL. Effective intradermal injections must form a bleb at the site. Two vaccines are currently available in the United States, RabAvert (Novartis, Chiron Behring GmbH) and Imovax (Sanofi Pasteur).36

In addition to vaccination, rabies immunoglobulin (RIG) should be given promptly in patients not previously vaccinated. RIG inhibits viral spread during the interval when antibodies are produced in response to the rabies vaccine.3 Human rabies immunoglobulin produced by Grifols (HyperRAB) is available, but the availability of Sanofi Pasteur’s Imogam has been limited.36

aDuring the 10-day observation period begin postexposure prophylaxis at the first signs of rabies in a dog, cat or ferret. If the animal exhibits clinical signs of rabies it should be euthanized and tested.
bThe animal should be euthanized and tested as soon as possible. Do not hold for observation. If laboratory studies are negative in the animal vaccine may be discontinued. Adapted from Manning SE, et al: Human rabies prevention United States 2008: Recommendations of the Advisory Committee on Immunization Practices MMWR Recomm Rep 57:1–28, 2008.
Human rabies immunoglobulin, 20 IU/kg, should be administered soon after the bite occurs and not more than 7 days after the first dose of rabies vaccine. Much of the RIG is injected into and around the site of the wound, with the remainder injected intramuscularly at a distance from the vaccine administration site. ACIP recommends the reduced four-dose vaccine schedule for postexposure prophylaxis in previously unvaccinated individuals. This regimen should start as soon as possible after the exposure, day 0, and should then be followed by repeated doses on days 3, 7, and 14. The dose is 1 mL of vaccine administered intramuscularly. The deltoid is the preferred site for adults; the anterolateral thigh is the preferred site in children. There is a diminished immunologic response to gluteal injection of vaccine, so this site should be avoided. The intradermal method requires two doses (0.1 mL) be administered in distant body parts on days 0, 3, 7, and 28.

Postexposure vaccination for previously vaccinated individuals requires wound care and a two-dose intramuscular vaccination (days 0 and 3) or four-dose intradermal vaccination (all on day 0). RIG is not needed in previously vaccinated individuals (Table 123.4)—those who have received ACIP- or WHO-approved PrEP or PEP or other vaccinations with documented rabies virus–neutralizing antibody response.

All US-licensed rabies vaccines are inactivated cell culture vaccines that can be administered to immunocompromised individuals. Patients with immunosuppressive disorders and those taking corticosteroids, immunosuppressive agents, and/or antimalarials may have a reduced response to the vaccine, necessitating a five-dose regimen. In this setting, serologic testing for neutralizing rabies antibody may be considered 4 weeks after the last vaccine dose to determine if a booster is necessary.

Adverse reactions to rabies vaccines include local reactions, mild systemic reactions, and immediate hypersensitivity reactions. Typical local reactions include pain, swelling, redness, and induration at the injection site. These symptoms are reported by 60% to 85% of recipients of the human diploid cell vaccine (HDCV) and by 11% to 57% of of recipients of the purified chick embryo vaccine (PCEV). From 6.8% to 55.6% and up to 31% of recipients of HDCV and PCEV, respectively, have reported systemic reactions, including gastrointestinal symptoms, headache, dizziness, and fever. Immediate hypersensitivity occurs in 1.2% of previously unimmunized HDCV recipients and in up to 6% of those previously immunized receiving HDCV as a booster. No deaths have been reported from recipients of the human diploid cell vaccine or purified chick embryo cell vaccine.

Rare severe neurologic reactions have occurred with PCEV and HDCV, but a causal relationship has not been verified. Guillain-Barré syndrome illness has been described with the use of both vaccines. Adverse reactions to human RIG are common, but these are primarily local reactions. Pain, induration, swelling, and erythema have been reported in 30% to 100% of injections. Headache is the most common systemic reaction to HRIG occurring in more than 50% of recipients. No deaths have been reported from human RIG.

Outside the United States, RIG is in short supply, and some countries do not use WHO-approved vaccines. Exposed travelers from these areas may require further vaccination on return to their native country. The CDC recommendations differ from those of WHO in that all PEP in unimmunized victims includes RIG in the United States but only category III wounds carry this recommendation from WHO.

**Wound Care**

Rabies virus is very sensitive to sunlight, soap, and drying. When performed within 3 hours of inoculation, scrubbing and flushing with benzylalkonium chloride, 20% soap solution, or Ivory soap is nearly 100% protective. Wounds from high-risk animals should be scrubbed with soap, water, and a virucidal agent (eg, povidone-iodine) and then flushed with saline or water. As with other mammalian bites, bacterial infection, cosmetic results, and tetanus prophylaxis need to be considered.

The bite location is a significant determinant of disease potential. Wounds to the face are at highest risk and require meticulous wound care. Highly vascular areas are high risk as well and include the head, neck, genitals, and hands.

### MANAGEMENT OF HUMAN RABIES INFECTION

Reversal of the disease process in rabies remains elusive, and palliative care continues to be the mainstay of therapy. Severe agitation is treated with sedation and analgesia. The basic mechanisms of pathogenesis are still poorly understood, making the discovery of a specific therapeutic drug unlikely. Intensive care therapy has prolonged the time until death, but care remains symptomatic. In resource-poor areas, aggressive intensive care therapy should include consideration of these factors: rabies vaccination prior to onset of disease, young age, rabies in previously healthy and immunocompetent individuals, initiation of treatment when neurologic signs are mild, New World bat variant rabies virus, and early detection of neutralizing anti–rabies virus antibodies in the serum and cerebrospinal fluid.

### KEY CONCEPTS

- Postexposure prophylaxis (PEP) for rabies should be administered to individuals exposed to the secretions of high-risk animals—raccoons, bats, skunks, foxes, coyotes, dogs along the Mexican border, and wild carnivores in rabies-endemic areas.
- PEP given strictly according to WHO or CDC guidelines is extremely effective in preventing rabies. PEP includes wound care, passive immunization with RIG, and active immunization with rabies vaccine.
- Discussion with public health officials is recommended to guide decisions regarding when PEP should be considered. The CDC clinician information line is 877-554-4625 or 800-CDC-INFO.

123.1. Which of the following is the only US state or territory that is rabies-free?
A. Alaska
B. Hawaii
C. Puerto Rico
D. Vermont
E. Washington, DC

Answer: B. There are no rabid bats or terrestrial mammals in Hawaii.

123.2. What domestic animal in the United States is most frequently reported as rabid?
A. Cat
B. Dog
C. Ferret
D. Gerbil
E. Monkey

Answer: A. Cats account for the largest number of domestic rabies cases in the United States. The median age of rabid cats and dogs is 1 year. Most human cases in the United States are from bats.

123.3. Which of the following statements concerning human rabies is true?
A. Encephalitic rabies is the most common form.
B. Humans with impaired immunity are more likely to have encephalitis.
C. It has a predilection for the neuromuscular junction.
D. Most cases present with paralysis.
E. The incubation period is independent of bite site.

Answer: A. Of human rabies cases, 80% are of the encephalitic (furious) form. Symptoms start as mild, with headache, fever, and paresthesia at the site of the bite, but rapidly progress over days to agitation, hypersalivation, hydrophobia, aphonia, coma, and death.

123.4. An 18-year-old man presents with lower extremity weakness of 2 days' duration. He has no past medical history and takes no medication. Which of the following factors would help differentiate Guillain-Barré syndrome from paralytic rabies?
A. Ascending pattern
B. Cranial nerve dysfunction
C. Diminished vision
D. Fever
E. Loss of deep tendon reflexes

Answer: D. Persistent fever from the onset of weakness, bladder dysfunction, and percussion myoedema suggest rabies. Preservation of sensory function is more likely with rabies.

123.5. Worldwide, which species is the dominant reservoir for rabies?
A. Bats
B. Dogs
C. Foxes
D. Raccoons
E. Skunks

Answer: B. Worldwide, dogs remain the largest reservoir, the most commonly infected, and the leading vector for human rabies.
Dogs are the most common cause of rabies in Asia and Africa where the vast majority of cases occur.

123.6. Postexposure care in a case of suspected rabies transmission should include which of the following?
A. B, C, and E
B. Active immunization
C. Immediate suturing of all wounds
D. Passive immunization
E. Vigorous soap and water scrubbing and then virucidal flushing

**Answer:** A. Aggressive wound cleansing may be the most important action in the rabies prophylaxis. Vigorous soap and water scrubbing and flushing should be followed by copious application of a virucidal agent, such as benzalkonium chloride or povidone-iodine. Passive immunization with RIG and active immunization with an approved World Health Organization vaccine should quickly follow. Wounds should initially be left open, with a planned delayed closure when appropriate.

123.7. Which of the following statements regarding the administration of human rabies immune globulin (HRIG) and human diploid cell vaccine (HDCV) is true?
A. HRIG and HDCV may be given at the same site.
B. HRIG may be given at any time after the vaccine is administered.
C. Postexposure prophylaxis is active only.
D. Prophylaxis does not change in a pregnant patient.
E. The gluteal region is the preferred vaccination site.

**Answer:** D. No protocol changes are indicated in pregnant patients. The deltoid is the preferred HDCV site to avoid injections into an area of more fat with less antibody production. It is critical that active and passive immunization occur. As much of the HRIG as possible should be infiltrated into the wound and the rest injected at a distant site. The immune globulin and vaccine should be injected at different sites. A typical plan is to inject HRIG into the wound, with the balance in one deltoid, and the vaccine administered into the opposite deltoid.

123.8. A 32-year-old emergency medicine intern crawls into bed after a 24-hour shift in the medical intensive care unit. Her 36-week pregnant spouse and 18-month-old daughter are asleep as she climbs into their bed. She is awakened from a dead sleep 3 hours later when her wife asks, “What is that brown thing on the ceiling?” Using a tennis racket, the bat is successfully encouraged out of the window. The intern calls you and asks if they need to be vaccinated. Your recommendations should include which of the following?
A. PEP (postexposure prophylaxis) is contraindicated in the pregnant spouse.
B. The 18-month-old and intern need PEP.
C. The spouse needs PEP.
D. They need better screens on their windows.

**Answer:** B. In spite of little evidence for a bite or scratch, the intern and 18-month-old fulfill requirements for PEP. Per Centers for Disease Control and Prevention recommendations, based on developmental staging, the 18-month-old girl cannot know whether an exposure may have happened. The intern does not explicitly meet the requirements for PEP because she is not a child, developmentally challenged, or intoxicated but, after a 24-hour shift, she was likely in a state of deep sleep and would not have been aware of her surroundings. Initiating PEP for her should be seriously considered. Although there is no contraindication for PEP during pregnancy, at 36 weeks, her spouse probably was not sleeping well and was certainly more aware of her surroundings than the intern. PEP should be considered for her but, if she is adamant that no bite or scratch occurred, it may be held.

123.9. A 3-year-old presents with a dog bite to the face. He was playing at his uncle’s house in Oregon and grabbed the tail of the family dachshund while the dog was eating. The dog turned and bit him on the face. The dog is fully vaccinated. The parents are very concerned about the risk of rabies. You explain that all the below are true except which of the following?
A. Dog bites in the United States carry a very low risk for rabies.
B. Effective canine rabies vaccine in the United States has existed since 1947, so only dogs in the border towns at the border between the United States and Mexico are at risk.
C. Wound care appropriate for a dog bite is the recommended management.
D. Immediate immunization with human rabies immune globulin (HRIG) and rabies vaccine should be initiated.

**Answer:** D. Domesticated antagonized dogs carry a very low risk of rabies infection, but may bite when irritated by a small child. Simple wound management is indicated.
CHAPTER 124
HIV Infection and AIDS

Sukhjit S. Takhar  |  Rachel L. Chin

**PRINCIPLES**

**Background and Epidemiology**

Acquired immunodeficiency syndrome (AIDS) is a pandemic caused by the human immunodeficiency virus (HIV). This disease is a relatively new phenomenon that has caused a tremendous degree of human suffering and has had an immeasurable impact on demographics, cultures, economics, and politics in most societies around the globe. There are an estimated 35 million people living with HIV infection worldwide, and 39 million people have died of AIDS-related illnesses. Significant strides have been made in areas of prevention and treatment, resulting in stabilization of the epidemic, and the annual number of new infections has steadily decreased since the 1990s. The decline in incidence of new cases of HIV infection and widespread use of highly active antiretroviral therapy (ART), have led to a decrease in AIDS-related deaths, resulting in an increase of the global prevalence of HIV/AIDS (Figs. 124.1 and 124.2).

Means of transmission of HIV and the demographic distribution of the virus vary from country to country. Sub-Saharan Africa is the epicenter of the pandemic, with 25.0 million adults and children living with HIV infection. Unprotected heterosexual intercourse with subsequent transmission of HIV to newborns and breast-fed babies (mother to child transmission) is the dominant mode of transmission worldwide, accounting for about 85% of all HIV infections. The main pattern of transmission in the higher income countries of North America and western and central Europe is in men who have sex with men. Other significant modes of transmission in these regions include injection drug use and paid unprotected sex.

**Pathophysiology**

HIV, a retrovirus from the lentivirus subfamily, is the cause of AIDS. There are two subtypes of HIV, HIV-1 and HIV-2. The most common cause of HIV infection and AIDS throughout the world is HIV-1. HIV-2, a closely related virus, is much less common and is typically seen in West Africa.

The mature HIV virion is a spherical structure with an outer envelope and inner core (Fig. 124.3). The core contains two copies of the RNA genome, enzymes (reverse transcriptase and integrase) and regulatory proteins. Surrounding the core is the viral membrane, containing the glycoproteins responsible for the attachment and entry of the virus into a CD4+ cell. In a multistep process, the HIV virion invades the host cell and integrates its genetic material into the host’s chromosome (Fig. 124.4). The infection begins with binding of the virus to the CD4+ host cell. The virus enters the cell by fusing its envelope with the target cell membrane. After internalization, reverse transcriptase forms viral DNA from the original RNA. The viral enzyme integrase then transports the newly formed viral DNA into the nucleus, where it integrates with human chromosomal DNA. Viral polypeptides and RNA are formed, and new infectious viral particles are created. This cycle continues with HIV infecting more CD4+ cells. Major targets of ART include reverse transcriptase, protease, integrase, and the CCR5 coreceptor.

The hallmark of HIV infection is CD4+ T cell destruction, leading to a deficient cell-mediated arm of the immune system. Humoral immunity is also impaired through B cell proliferation and production of abnormal antibodies, making HIV-infected individuals more vulnerable to infections by encapsulated bacteria. HIV infection also leads to a chronic immune activation. Ongoing viremia, along with proinflammatory cytokines, B cell proliferation, and hypergammaglobulinemia, leads to a chronic inflammatory state that contributes to cardiovascular disease, cancer, and other chronic diseases in long-term, HIV-infected individuals. Increased immune activation persists, even in patients with immune reconstitution on antiretroviral therapy.

**Risk Factors for HIV Transmission**

HIV has been isolated from a wide range of body fluids, including semen, vaginal secretions, lymphocytes, cell-free plasma, cerebrospinal fluid (CSF), tears, saliva, urine, and breast milk. However, only semen, blood, vaginal secretions, and breast milk are significantly infectious. For transmission to occur, these fluids must come into contact with damaged tissue or with a mucous membrane or be directly injected into the bloodstream.

The highest risk exposure is transfusion with HIV-positive blood. Other factors associated with an increased risk of HIV transmission include exposure to serum with a high viral load, lack of male circumcision, and presence of an ulcerative, sexually transmitted infection. The risk of transmission of HIV varies by the type of sexual contact: it is 1% to 30% for receptive anal intercourse, 0.1% to 10% for receptive vaginal and insertive anal intercourse, and 0.1% to 1% for insertive vaginal intercourse.

After transmission, the virus replicates in the mucosal surface or lymphoid tissue at the site of entry in lymphocytes and macrophages. If enough cells are infected, the virus spreads to draining lymph nodes and infection is established, usually within 48 to 72 hours.

**CLINICAL FEATURES**

The clinical manifestations of HIV infection are varied. Patients may present to the emergency department (ED) with acute HIV infection, medication side effects, or unusual opportunistic infections from advanced AIDS. The natural history of the disease has been altered significantly with the advent of ART. However, there still is no cure. In addition to causing progressive immune dysfunction, chronic HIV infection causes an ongoing inflammatory state, leading to the development of numerous manifestations that have not been classically thought of as HIV disease. These include malignant neoplasms, coronary artery disease, and neurocognitive disorders. The dramatic immune recovery that is seen with modern ART can also cause an inflammatory syndrome that resembles the original opportunistic infection. Overall, the spectrum of HIV infection is changing because of longer life expectancy and better treatment. However, many patients still
Primary HIV Infection

Primary infection with HIV often causes an acute, self-limited viral infection. The most common findings are mononucleosis-like symptoms that consist of fever, pharyngitis, and lymphadenopathy. This usually occurs 2 to 6 weeks after transmission. During this time, the virus is actively replicating, and antibodies to HIV have not been produced. The virus has many potential targets, and viral loads are often enormous. The diagnosis of acute HIV infection has significant public health benefits. Patients with acute HIV infection transmit the infection disproportionately;
these patients often do not know that they are infected, and their viral load may be in the range of millions of RNA copies per milliliter.

Symptoms are nonspecific and are often not recognized as signs of HIV infection. The illness usually lasts for less than 2 weeks, although some patients may have a prolonged course. Cases of encephalitis, Guillain-Barré syndrome, and mononeuritis have occurred. CD4⁺ counts also transiently drop, occasionally to the level at which opportunistic infections can occur. Among others, *Pneumocystis jiroveci* pneumonia (PCP), toxoplasmosis,
With a CD4 dysfunction is severe and, without ART, survival is short. Those of an AIDS-defining condition (Box 124.1). At this level, immune 200 cells/µL, for toxoplasmosis, when CD4 µ+ Prophylaxis is started for PCP when CD4 nistic infections. Some infections are so common in patients with are at much higher risk for death and development of opportu - nity. Patients, however, typically lose approximately 80 CD4 protein derivative. The risk of opportunistic infection in relation to the CD4+ cell count is progressive rather than an all or none phenomenon.

**Initial Evaluation**

HIV-infected patients are at risk for some of the same infections and medical problems as noninfected patients, but they are more

**AIDS-Defining Conditions**

- Bacterial infections, multiple or recurrent
- Candidiasis of bronchi, trachea, or lungs
- Candidiasis of esophagus
- Cervical cancer, invasive
- Coccidioidomycosis, disseminated or extrapulmonary
- Cryptococcosis, extrapulmonary
- Cryptosporidiosis, chronic intestinal (>1 mo duration)
- Cytomegalovirus disease (other than liver, spleen, or nodes), onset at age >1 mo
- Cytomegalovirus retinitis (with loss of vision)
- Encephalopathy, HIV related
- Herpes simplex: chronic ulcers (>1 mo duration) or bronchitis, pneumonitis, or esophagitis (onset at age >1 mo)
- Histoplasmosis, disseminated or extrapulmonary
- Isosporiasis, chronic intestinal (>1 mo duration)
- Lymphoma, Burkitt’s (or equivalent term)
- Kaposi’s sarcoma
- Lymphoma, immunoblastic (or equivalent term)
- Lymphoma, primary, of brain
- Mycobacterium avium complex or Mycobacterium kansasii, disseminated or extrapulmonary
- Mycobacterium tuberculosis of any site, pulmonary, disseminated, or extrapulmonary
- Mycobacterium, other species or unidentified species, disseminated or extrapulmonary
- Pneumocystis jiroveci pneumonia
- Pneumonia, recurrent
- Progressive multifocal leukoencephalopathy
- Salmonella septicaemia, recurrent
- Toxoplasmosis of brain, onset at age >1 mo
- Wasting syndrome attributed to HIV

Isoniazid is given to patients with a positive response to purified protein derivative. The risk of opportunistic infection in relation to the CD4+ cell count is progressive rather than an all or none phenomenon.
vulnerable to opportunistic and unusual infections. Knowledge of the CD4 count, along with the patient’s clinical presentation, is critical in ED management. Before ART, patients were primarily hospitalized for opportunistic infections. Patients with HIV infection are now dying of diseases that were not traditionally considered as an AIDS disease, such as heart disease, liver failure, and non–AIDS-related cancers.4

The current CD4 count is a marker of the degree of immunosuppression and is critical background information for the interpretation of signs and symptoms. However, many patients have undiagnosed HIV infection, and they often present in later stages of disease. Others may not be taking ART because of issues involving access to care, difficulties with medication adherence, or viral resistance to ART. Opportunistic infections such as PCP, disseminated mycobacterial infections, cryptococcal meningitis, and CMV disease do not occur until the CD4 count is dramatically reduced. A total lymphocyte count may provide a rough approximation of the absolute CD4 count; a count between 1000 and 2000 cells/µL appears to be a reasonable surrogate of significant immunosuppression. Acute illness will decrease peripheral lymphocyte counts and thus limits the value of the peripheral lymphocyte count as a diagnostic aid in an acute setting. However, an ED study has shown that patients with a peripheral lymphocyte count below 950 cells/µL are highly likely to have AIDS.6

Certain clinical features suggest the possibility of a new diagnosis of HIV infection. A careful look at the skin and in the mouth may be revealing; certain skin findings, such as oral hairy leukoplakia and Kaposi’s sarcoma, are found almost exclusively in HIV-infected individuals. Unexplained oral candidiasis is often the initial presenting symptom in someone with an undiagnosed HIV infection.

**Clinical Manifestations by Organ System**

**Cardiovascular Manifestations**

Cardiovascular manifestations of HIV infection vary greatly, depending on the patient’s immune status and whether the patient is receiving ART. Patients with advanced HIV infection can have a constellation of cardiac manifestations, including pericarditis, myocarditis, cardiomyopathy, pulmonary vascular disease, pulmonary hypertension, valvular disease, and neoplastic involvement of the heart. Purulent pericarditis and cardiac tamponade are potentially lethal clinical manifestations of cardiovascular disease in patients with AIDS; *Mycobacterium tuberculosis* is often the causative organism, especially in low-resource countries.

The success of ART has led to prolonged survival in patients with HIV. Cardiovascular disease is now the major cause of morbidity and mortality. HIV-infected patients have a 50% increased risk of acute coronary syndrome compared to the general population, after adjustment for risk factors.7 It is unclear whether this is the result of unmeasured traditional risk factors, the HIV infection itself, a complication of ART, or a combination of these factors. Patients receiving ART suffer from a number of metabolic abnormalities (eg, hyperglycemia, hyperlipidemia, lipodystrophy) and accelerated atherosclerosis, which may increase their risk for cardiovascular disease and acute coronary syndrome. Studies have shown that the virus alone is associated with dyslipidemia, endothelial damage, inflammation, and hypercoagulability.7-10 Discontinuing ART has been shown to result in systemic inflammation, coagulation cascade activation, an increase in biomarkers associated with endothelial activation, and increased risk of major cardiovascular events. Antiretroviral agents cause varying degrees of dyslipidemia. Protease inhibitors, particularly ritonavir in higher doses, can especially be a problem. Nonnucleoside reverse transcriptase inhibitors (NNRTIs) are associated with increases in low-density lipoprotein cholesterol and total cholesterol but also a significant increase in high-density lipoprotein cholesterol. Modern regimens appear to be less toxic. Despite the reality that ART is likely to contribute to the development of coronary artery disease, the benefits of therapy outweigh the risks of accelerated atherosclerosis.

**Pulmonary Manifestations**

Pulmonary diseases have been the most important complications of HIV/AIDS. Infectious and noninfectious pulmonary diseases are more common in those with HIV infection compared to

uninfected individuals. The most frequent respiratory infections in people with HIV infection are upper respiratory tract infections and acute bronchitis. The incidence of lower respiratory tract infections increases as CD4+ counts decline. Potential causes of lower respiratory tract infections include viruses (influenza, respiratory syncytial, parainfluenza), bacteria, and fungi (Table 124.3). Bacterial pneumonia is more frequent in people infected with HIV than in uninfected persons; the most common organism is *Streptococcus pneumoniae*. The incidence of PCP also increases as the CD4+ count drops below 200 cells/µL.

A number of noninfectious causes of pulmonary disease are associated with HIV infection. Although the incidence is greatly reduced in the era of ART, pulmonary manifestations of Kaposi’s sarcoma and non-Hodgkin’s lymphoma can occur. HIV-infected patients also appear to be at increased risk for lung cancer, emphysema, cryptogenic organizing pneumonia, sarcoidosis, drug hypersensitivity, primary effusion lymphoma, foreign body granulomatosis, and lymphocytic interstitial pneumonia.

Diagnostic evaluation of patients with HIV infection who present with respiratory complaints should be based on their HIV disease stage (Table 124.4). Specific algorithms are difficult because of geographic differences in epidemiology. Evaluation includes pulse oximetry, chest radiography, and complete blood count. Additional tests may include arterial blood gas analysis to determine the need for corticosteroids in patients with PCP, levels of serum lactate dehydrogenase in patients with P. jiroveci pneumonia, elevated in PCP, 1,3-β-D-glucan (elevated in PCP), β-d-glucuronidase (elevated in PCP), 1,3-D-glucan, and sputum studies (including Gram staining, acid-fast bacillus, and staining for *P. jiroveci*). Blood cultures should be considered before antibiotic therapy initiation; an aggressive search for the pathogen is generally recommended in patients with HIV infection.

PCP is one of the most common AIDS-defining opportunistic infections. With the widespread use of ART, as well as chemoprophylaxis against PCP in patients with CD4+ counts below 200 cells/µL, the incidence of PCP in developed countries has greatly

---
declined. The clinical presentation of PCP is characterized by the gradual onset of fever (79% to 100% of cases), cough (95%), and progressive dyspnea (95%). The cough is nonproductive; although sputum production does not exclude this diagnosis, and patients can be coinfect with a bacterial pneumonia. Some patients, especially those taking nonsystemic prophylaxis (eg, aerosolized pentamidine), may have extrapulmonary manifestations of PCP, such as hepatosplenomegaly, skin lesions, and ocular lesions. The most common associated laboratory abnormalities are a CD4+ count below 200 cells/µL and elevated lactate dehydrogenase level. Whereas chest radiographs can be normal, they usually show diffuse, bilateral, interstitial, or alveolar infiltrates (Fig. 124.5). High-resolution computed tomography (CT), which has a high sensitivity for PCP, often reveals ground glass or cystic lesions; a normal scan makes the diagnosis of PCP very unlikely (Fig. 124.6). The definitive diagnosis is made by isolation of the organism, commonly from respiratory specimens obtained by sputum induction, bronchoalveolar lavage, or endotracheal aspiration.

Double-strength trimethoprim-sulfamethoxazole (TMP-SMZ) administered orally daily is the preferred PCP prophylaxis. TMP-SMZ is also the preferred treatment of PCP; the route is dependent on the severity of disease. There are a number of other possible regimens for those who are intolerant (Table 124.5).

Hypoxic patients (partial pressure of oxygen \( \leq 70 \) mm Hg or an alveolar-arterial oxygen gradient \( \geq 35 \) mm Hg) receive significant benefit from concurrent corticosteroid treatment. Hypoxic patients should receive a 21-day prednisone taper in addition to antibiotic therapy.

The risk of tuberculosis (TB) increases with declining immune function; it doubles within the first year after HIV seroconversion. Patients with HIV infection are more likely to develop active TB from reactivated latent infection, and TB co-infection increases the risk of progression to AIDS or death.

Clinical manifestations and radiographic findings of TB vary by the degree of underlying immunosuppression of the patient. Patients with early HIV infection and TB have presentations similar to those of individuals without HIV infection; they often have classic symptoms of pulmonary TB, such as fever, cough, weight loss, malaise, and night sweats. The typical radiographic findings of cavitation in the upper lung fields are usually present. With worsening immune function, there is less likelihood of pulmonary cavitation. In these cases, atypical radiographs are more common, such as pulmonary infiltrates without preference for the upper lung fields, and normal radiographs have been reported. With advanced HIV infection and severe immunosuppression, there is greater risk of extrapulmonary and disseminated TB.

In patients thought to have TB regardless of radiographic findings, diagnostic tests should be pursued, and the patient should be placed in respiratory isolation. Evaluation of extrapulmonary disease includes specimens of suspected areas of involvement (eg, CSF, lymph nodes, pleural fluid, pericardial fluid, blood, urine). The treatment of TB in people with HIV infection is complicated, and drug interactions between ART and anti-TB therapy are severe and common. After initiation of anti-TB therapy, the patient requires close monitoring for assessment of adequate treatment response and for observation of signs of immune reconstitution inflammatory syndrome (IRIS), a complication more common in patients with CD4+ counts below 200 cells/µL.

Although outpatient therapy is possible, most HIV-infected patients with a low CD4+ cell count and respiratory complaints require hospitalization. Bronchoscopy and high-resolution CT chest scanning are often required to make the definitive diagnosis. Patients with presumed bacterial pneumonia require treatment with antibiotics that cover the usual community-acquired organisms.

**Oropharyngeal and Gastrointestinal Manifestations**

Oropharyngeal and gastrointestinal (GI) diseases often complicate HIV infection. HIV-infected patients with GI symptoms may present with common abdominal disease or may have opportunistic infections, malignant neoplasms, or medication side effects. Patients receiving ART may suffer treatment-related adverse gastrointestinal events, including pancreatitis, hepatic steatosis, lactic acidosis, and drug-induced hepatotoxicity. Furthermore, a number of patients with HIV infection have concomitant hepatitis B virus (HBV) or hepatitis C virus (HCV) infection and may also have GI manifestations from these causes as well. Although improvements have been noted, end-stage liver disease remains a common cause of mortality in HIV-infected patients.4,15

As in other organ system disease, patients with higher CD4+ counts tend to be infected by common, more pathogenic bacteria. Patients with CD4+ counts below 100 cells/µL are more likely to have opportunistic infections and suffer from hepatobiliary problems, such as acalculous cholecystitis.

Primary HIV infection has a variety of oropharyngeal manifestations, including pharyngitis and severe aphthous ulcers. With progressive immunodeficiency, the pathogens change. Thrush, caused by *Candida*, is an extremely common opportunistic infection and is often the first manifestation of HIV infection. Oral hairy leukoplakia, caused by Epstein-Barr virus (EBV), is manifested as raised white lesions on the side of the tongue. Unlike in thrush, the lesions cannot be scraped off and are not responsive to topical antifungal agents. Kaposi’s sarcoma, which can occur in the mouth, is usually found on the palate.

Esophagitis may occur in HIV-infected patients, particularly those with CD4+ counts below 100 cells/µL. Patients present with dysphagia or odynophagia. The most common cause of esophagitis in patients with HIV infection is *Candida*. Other potential causes include herpes simplex virus, CMV, and deep aphthous ulcers. The underlying cause can be confirmed by endoscopy with biopsy. Given that biopsy is invasive and fungal sphenitis common, most patients with esophagitis first undergo a course of fluconazole for empirical treatment of *Candida* infection; a clinical response should occur within 5 to 7 days. Gastroesophageal reflux is another common complaint, and treatment is with antacids. However, certain antiretrovirals, such as atazanavir, require an acidic environment to aid in absorption. Consideration of potential drug interactions is important when new medications are started in HIV-infected patients.

Small or large bowel enteritis, characterized by abdominal pain, cramping, diarrhea, dehydration, and fever, is a common problem and can be caused by a number of underlying factors. Bacterial infections are the usual offenders, such as *Clostridium difficile* and *Salmonella, Shigella, Campylobacter*, and *Yersinia* spp. Patients with advanced immunosuppression can have chronic diarrhea, often from opportunistic infections with the parasites *Cryptosporidium*, *Isospora*, and microsporida. CMV causes large bowel enteritis and generally occurs in severely immunosuppressed patients with CD4+ counts below 50 cells/µL. In developing countries, TB should also be considered a cause of abdominal disease in patients with HIV infection. Malignant diseases, such as lymphoma and Kaposi’s sarcoma, can affect the bowels. Kaposi’s sarcoma lesions in the GI tract can cause massive bleeding and obstruction. The evaluation for diarrhea often involves laboratory stool studies (ova and parasite, *C. difficile* toxin, bacterial culture, modified acid-fast staining) and, occasionally, colonoscopy. Therapy is usually supportive, maintaining hydration; symptoms often persist until immune reconstitution.

Disseminated opportunistic infections can also involve the liver, including MAC and *Bartonella* infections. AIDS-related cholangiopathy, biliary obstruction from infection-associated strictures of the biliary tract, is seen with severe immunosuppression. However, noninfectious causes, such as cholecytitis, have become more common.

**Central Nervous System Manifestations**

The differential diagnosis of patients who present with headaches, abnormal findings on neurologic examination, or change in mental status varies on the basis of the current status of their immune system and results of neuroimaging. Common problems include cryptococcal meningitis, toxoplasmosis, primary central nervous system (CNS) lymphoma, and progressive multifocal leukoencephalopathy. Many patients with untreated HIV infection, symptomatic or not, will have abnormal CSF findings.

HIV itself is a neurotropic virus, and patients with acute infection can present with aseptic meningitis with complaints of fever, headaches, and meningismus. There usually is lymphocyte-predominant, moderate pleocytosis. Syphilis has also reemerged, and CNS infection can occur at any stage of HIV infection.

*Cryptococcus neoformans* is the most common cause of meningitis in patients with AIDS. It usually affects patients who are profoundly immunosuppressed, with CD4+ counts below 100 cells/µL. The disease is subacute, and patients present with fevers, malaise, and headache. Later in the course, because of increased intracranial pressure, patients experience vomiting and altered mental status. *Cryptococcus* often does not cause a significant inflammatory response, and meningeal signs are frequently absent. A lumbar puncture is diagnostic, demonstrating elevated opening pressures (70% with pressures > 200 mm Hg), presence of cryptococcal antigen (CRAG), and low white blood cell count in the CSF (typically, <50/µL in the CSF). Serum CRAG testing is readily available, sensitive, and especially useful in resource-poor settings.16 If the serum CRAG is negative, it will unlikely be positive in the CSF and not the cause of cryptococcal meningitis. Poor prognostic factors for cryptococcal meningitis are altered mental status, absence of CSF pleocytosis, CSF antigen titers greater than 1:1024, and a positive serum fungal culture.17,18 These signs are indicative of a high organism burden, elevated CSF pressure, and lack of an inflammatory response. If left untreated, cryptococcal meningoencephalitis is fatal. Therapy involves three phases—induction, consolidation, and maintenance. If the patient can tolerate it, aggressive initial treatment with 2 weeks of amphotericin B and flucytosine is recommended.19 Fluconazole is used for the consolidation phase and is continued until immune reconstitution (CD4+ count > 100 cell/µL for more than 1 year). Elevated intracranial pressure is treated with repeated lumbar punctures; on occasion, a lumbar drain is needed. Cryptococcal meningitis immune reconstitution syndrome can cause rapid clinical deterioration. A multicenter randomized trial has shown improved survival when ART is started 5 weeks after antifungal treatment compared to 1 to 2 weeks in those with risk factors.20

Patients may present with focal CNS lesions. Severely immunocompromised hosts (CD4+ count < 200 cells/µL) are likely to have opportunistic infections or AIDS-associated tumors (Table 124.6). In developed countries, common causes of mass effect are toxoplasmosis and EBV-related primary CNS lymphoma; in developing countries, the cause is more likely to be tuberculosis. Toxoplasmosis is caused by reactivation of latent infection by the parasite *Toxoplasma gondii*. Most infected patients have a CD4+ count below 100 cells/µL. Patients present with signs of increased

photon emission CT can help differentiate among toxoplasmosis, lymphoma, and progressive multifocal leukoencephalopathy. The gold standard for the diagnosis of CNS mass lesions remains brain biopsy. Corticosteroid therapy can cause false-negative results on brain biopsies in patients with lymphoma, and therefore the use of corticosteroids should be limited to patients with life-threatening mass lesions.21

Renal Manifestations

The two main categories of HIV-related kidney disease are HIV-associated nephropathy (HIVAN) and HIV immune complex kidney disease. HIVAN is a form of focal glomerulosclerosis that usually occurs in untreated individuals of African descent.22 Proteinuria, often severe, and an elevated creatinine concentration occur. Some patients recover renal function with ART, but many progress to end-stage renal disease and require dialysis. Transplantation is now widely accepted for patients with stable HIV infection.22 ART can also affect the kidney. Indinavir, although less commonly used in industrialized countries, is associated with renal calculi. Tenofovir can cause acute renal failure, a Fanconi-like intracranial pressure, such as headaches, confusion, lethargy, and seizures. Lesions are typically multiple and ring enhancing on CT. Although the definitive diagnosis is made after a brain biopsy, patients who are serologically positive for toxoplasmosis are usually treated empirically with pyrimethamine and sulfadiazine, keeping in mind that toxoplasmosis is much less common in patients who have been receiving TMP-SMZ prophylaxis for PCP. Most patients will show radiographic improvement in 2 weeks; response to treatment will obviate the need for a brain biopsy (Fig. 124.7).

Primary CNS lymphoma often looks identical to toxoplasmosis on magnetic resonance imaging (MRI) or CT scans. It also occurs with profound immunosuppression (CD4+ count < 50 cells/µL). EBV is the cause of primary CNS lymphoma, and a polymerase chain reaction (PCR) analysis of the CSF, looking for the virus, has become an integral step in the evaluation of mass lesions. Treatment involves ART and chemotherapy.

Progressive multifocal leukoencephalopathy, caused by the JC virus, is characterized by demyelinating lesions in the CNS. The diagnosis is suggested by nonenhancing, hypodense lesions on CT or MRI, with a CSF PCR assay positive for JC virus. Advanced imaging with positron emission tomography, MRI, and single-photon emission CT can help differentiate among toxoplasmosis, lymphoma, and progressive multifocal leukoencephalopathy.

CNS, Central nervous system; PCR, polymerase chain reaction.
syndrome, and nephrogenic diabetes insipidus. Medications used to treat opportunistic infections can cause acute renal failure; amphotericin, pentamidine, and foscarnet are especially notorious.

**Rheumatologic and Orthopedic Manifestations**

HIV-infected patients are susceptible to the same types of orthopedic injuries and musculoskeletal disorders as patients without HIV infection, but there are certain conditions specific to HIV infection. Disseminated diseases such as TB are much more common in HIV-infected patients than in noninfected patients. Patients with HIV infection are prone to extrapulmonary manifestations, including septic arthritis, spondylitis, osteomyelitis, and bursitis. In general, however, septic arthritis is relatively uncommon in HIV-infected individuals. Risk factors include injection drug use and hemophilia. The most common organism involved is *Staphylococcus aureus*. Disseminated gonococcus causing septic arthritis is another possibility, especially in sexually active individuals. Unusual and atypical infections occur in late-stage AIDS. Bacillary angiomatosis, for example, is caused by *Bartonella quintana* and causes disseminated disease affecting the skin, lymph nodes, liver, and CNS and can cause long bone osteomyelitis.

Fractures of the hip, spine, and wrist are more common in HIV-infected individuals because they have lower bone mineral density than that of age-matched controls. Osteonecrosis, especially of the femoral head, is common. Predisposing factors include corticosteroid use, ethanol abuse, and hypertriglyceridemia.

HIV-related polyarthritis can occur at any stage of infection. These patients may have proximal muscle weakness, myalgias, and fatigue. Medications, especially nucleotide reverse transcriptase inhibitors (NRTIs), such as azidothymidine (AZT), can be toxic to the mitochondria and are common causes of polyarthritis. Myopathies, spondylarthritides, pyomyositis, and HIV-associated arthritis are also common musculoskeletal problems. Reactive arthritis and other seronegative arthropathies are common, although it is unclear if this is because of sexual activity, generalized immune suppression, or the inflammatory response from the virus itself.

**Fig. 124.7.** Brain magnetic resonance image of a 38-year-old man with AIDS and *Toxoplasma* encephalitis. (From Mandell GL, et al, editor: Mandell, Douglas, and Bennett’s principles and practice of infectious diseases, ed 7, Philadelphia, 2010, Elsevier/Churchill Livingstone.)

**Hematologic Manifestations**

HIV infection can cause anemia, thrombocytopenia, and leukopenia. Thrombocytopenia can occur in any stage of HIV infection. The cause is often immune-related, presenting as a disease process similar to idiopathic thrombocytopenic purpura; the treatment is ART. Thrombotic thrombocytopenic purpura is also well described in HIV-infected patients and tends to occur at later stages of disease.

Anemia and leukopenia occurs in later stages of HIV infection. Various medications can cause bone marrow toxicity; AZT, TMP-SMZ, and ganciclovir are common offenders. Systemic fungal infections and mycobacterial disease such as disseminated MAC disease can infect the bone marrow and decrease all three cell lines. Nutritional deficiencies, such as folate and vitamin B₁₂, are also common.

AIDS-related lymphoma (Hodgkin’s and non-Hodgkin’s) occurs more frequently in patients with advanced HIV infection. Most non-Hodgkin’s lymphomas are of B cell origin and tend to be more aggressive in HIV-infected than in noninfected patients. CNS lymphomas and Burkitt’s lymphoma are almost always associated with EBV, and primary effusion lymphoma is associated with human herpesvirus 8. The treatment involves standard chemotherapy and ART.

**Cutaneous Manifestations**

Dermatologic manifestations of HIV infection are extremely common, occurring throughout the course of HIV infection. Some skin findings are manifested early in the disease; others, found later, can be suggestive of profound immunosuppression (Box 124.2). Skin problems increase as HIV infection progresses. Recognition of HIV-related dermatologic conditions can lead to early diagnosis and can help the emergency clinician gauge the patient’s immune status (Box 124.3).

Acute HIV infection often is manifested with a generalized maculopapular or morbilliform rash shortly after the onset of fevers. Oral ulcers, lesions on the palms and soles, and mucosal lesions can all be present. Aside from HIV itself, a variety of viruses can involve the skin. Herpes simplex virus infections are often more severe and recur frequently. Chronic ulcerating herpes simplex occurs later in the disease course and is an AIDS-defining opportunistic infection. Other common viral diseases include molluscum contagiosum, human papillomavirus infection, and oral hairy leukoplakia.

Kaposi’s sarcoma, a vascular neoplasm, is the most common AIDS-related malignant disease in the United States, and the skin is the most commonly involved organ. Lesions are violaceous patches, nodules, or plaques (Fig. 124.8). Bacillary angiomatosis is manifested with lesions that resemble those of Kaposi’s sarcoma.

**HIV-related polymyositis** can occur at any stage of infection. These patients may have proximal muscle weakness, myalgias, and fatigue. Medications, especially nucleotide reverse transcriptase inhibitors (NRTIs), such as azidothymidine (AZT), can be toxic to the mitochondria and are common causes of polymyositis. Myopathies, spondylarthritides, pyomyositis, and HIV-associated arthritis are also common musculoskeletal problems. Reactive arthritis and other seronegative arthropathies are common, although it is unclear if this is because of sexual activity, generalized immune suppression, or the inflammatory response from the virus itself.
**DIAGNOSTIC CONSIDERATIONS**

**Differential Diagnosis**

The possibility of HIV infection in patients presenting to the ED must be considered on a case by case basis. HIV infection should be considered in any patient who presents with unusual or recurrent serious infections without another explanation, especially patients with risk factors for HIV infection, such as IV drug users (IVDUs) and high-risk sexual practices. Although the opportunistic infections associated with AIDS can also occur in the absence of HIV infection, they usually develop in patients with some form of immunosuppression. HIV infection should also be considered in younger patients who develop conditions that typically don’t occur until later in life, such as herpes zoster.

**Diagnostic Testing**

**HIV Testing**

The diagnosis of HIV infection involves the detection of specific antibodies or viral antigens (see Table 124.1). Laboratory detection of HIV infection is a two-step process. The first step is a screening test; if the result is positive, a confirmatory test is performed.

The balance between public health and patient confidentiality has been an issue surrounding HIV testing and reporting. Most states and hospitals have developed policies related to these concerns. Regardless, testing should be done in a confidential manner, with appropriate follow-up and counseling.

With the advent of enhanced testing capabilities as well as the push to diagnose existing cases of HIV infection in difficult to reach populations, some experts have recommended routine screening tests. Advantages of testing in the ED include increased detection of HIV infection in difficult to reach populations and earlier diagnosis of HIV infection, allowing earlier ART implementation and therefore decreased viral transmission.

In 2006, the CDC published revised recommendations for HIV testing in health care settings, including hospital EDs. This report recommended the use of diagnostic HIV testing and opt-out HIV screening in routine clinical care. Routine screening is recommended for 13- to 64-year-old patients, all patients who require TB treatment, those seeking treatment for sexually transmitted infections, and all pregnant women. Repeat annual screening is recommended for people at high risk. Providers should encourage patients to have HIV screening before the initiation of sexual relationships and after occupational exposures. Recommendations specify that consent should be obtained for HIV testing, pretest information should be shared with patients, and those responsible for the patient’s care should be notified verbally of the planned testing.

**MANAGEMENT**

ART has led to dramatic reductions in morbidity and mortality from opportunistic diseases and non-AIDS conditions. The goal of therapy is to suppress viral replication and reconstitute the immune system. Primary and secondary prophylaxis against opportunistic infections can be safely stopped with a return of CD4+ cells. The best evidence for successful treatment is in those patients with CD4+ counts below 350 cells/µL. However, CD4+ counts below 500 cells/µL indicate that there is an impairment of immune function, and recent guidelines have recommended treatment of asymptomatic patients at any stage.

Antiretroviral therapies target the major viral enzymes—reverse transcriptase, protease, and integrase—and their attachment and fusion sites. ART involves the use of three active drugs,
usually two NRTIs and another agent, often an integrase strand transfer inhibitor, protease inhibitor, or NNRTI. Zidovudine, an NRTI, was the first drug released. Several NRTIs are currently available and have been approved by the US Food and Drug Administration for the treatment of HIV infection. Protease inhibitors, released in 1995, revolutionized the treatment of HIV infection and were the beginning of ART. NNRTIs are also commonly a part of the three-drug regimen. The initial regimen of ART needs to be individualized. Factors to consider in choosing a regimen include tolerability, viral resistance, dosing frequency, cost, and comorbidities.

Side effects from antiretroviral medications are extremely common. Protease inhibitors are notorious for GI side effects; most cause nausea and diarrhea. The NRTIs are mitochondrial toxic and can cause pancreatitis and hepatitis. Nevirapine, an NNRTI, can cause hepatic necrosis. Atazanavir causes a Gilbert-like syndrome. Efavirenz is commonly associated with self-limited neuropsychiatric problems.

**Postexposure Prophylaxis**

All efforts should be made to minimize the potential for occupational exposure to body fluids. When exposure to body fluids occurs, however, the risk of acquiring HIV infection is low. Before ART, a large study examining HIV transmission from needle stick injuries to health care workers showed that transmission occurred in only 1 of 300 cases (0.33%), and there were no known cases of transmission through intact skin. Currently, with postexposure prophylaxis (PEP) using ART, the risk of transmission is thought to be greatly reduced. Factors associated with increased risk of transmission from occupational exposure involving needle stick injuries include depth of injury, injury from a device visibly contaminated with the patient’s blood, and needle stick into a vein or artery.

Recommendations regarding the use of PEP are based on the type of injury and body fluid involved. Body fluids of concern include semen, vaginal secretion, and any fluid contaminated with visible blood. Potentially infectious body fluids include CSF and synovial, pleural, peritoneal, pericardial, and amniotic fluids. Unless they contain blood, the following fluids are not considered infectious for HIV: vomitus, feces, nasal secretions, saliva, sputum, sweat, tears, and urine. Low-risk injuries include those involving solid needles (eg, suture needles), those that are superficial, and those involving a low-risk source patient or body fluid. High-risk injuries include those involving hollow-bore needles with visible blood and per- cutaneous injury from a needle that was in an artery or vein of the source patient. Unless a mucocutaneous exposure involves large volumes of blood from a source patient with a plasma HIV viral load more than 1500 copies/µL, mucocutaneous exposures are considered to be low risk. Transmission is estimated to be as low as 0.096% (1/1000) for a splash of infectious body fluid to mucous membranes or broken skin.

The initial response to an exposure is immediate cleansing of the exposed or injured site; soap and water can be used for intact skin, and virucidal antisepsic agents, such as alcohol-based hand hygiene agents, can be used for small punctures and wounds. Mucosal surfaces and eyes should be flushed with copious amounts of water. Efforts should be made to document clinical information about the source patient, including risk factors and previous test results for HIV, HBV, and HCV, as well as to provide a description of the exposure and the time it occurred.

In 2013, the US Public Health Services updated their guidelines on managing occupational exposures to HIV. The new guidelines recommended three or more antiretroviral drugs for all occupational exposures to HIV.

Preferred regimens for PEP mirror the treatment of HIV—three-drug combination therapy with a dual NRTI backbone plus an integrase strand transfer inhibitor (INSTI), boosted protease inhibitor, or NNRTI. A commonly recommended regimen with a low toxicity profile and minimal drug interaction is tenofovir-emtricitabine (Truvada), along with the INSTI raltegravir. Other regimens include tenofovir-emtricitabine plus atazanavir or tenofovir-emtricitabine plus darunavir with ritonavir. Obtaining expert consultation should be considered for those with high-risk exposure, with comorbidities, or exposed to a drug-resistant virus, and those who present 72 hours or more after exposure. The National Clinicians’ Post-Exposure Prophylaxis Hotline (PEPline) can be contacted at 888-448-4911 if local expertise is not immediately available.

If the exposed person is to receive PEP, the goal is to initiate therapy within 1 to 2 hours after exposure; the efficacy of PEP greatly decreases after 24 to 36 hours. Follow-up HIV testing should occur at 6 weeks, 3 months, and 6 months. If fourth-generation HIV antigen-antibody assays are used, HIV testing is performed at baseline, 6 weeks, and 4 months after exposure. Testing can be concluded 4 months after exposure as opposed to 6 months with other HIV antibody assays. An additional test at 12 months can be considered for those exposed to source patients co-infected with HIV and HCV. Reevaluation of the patient within 72 hours of exposure is recommended. PEP should be continued for 28 days or until the source patient tests negative for HIV.

Some patients may present after possible exposure to HIV/AIDS with concern about the potential of transmission. Possible means of exposure include sexual contact, injection drug use, and exposure to body fluids through broken skin or mucous membranes. The risk of transmission varies with the means of exposure. For sexual exposure, receptive anal intercourse carries a higher risk of transmission among men who have sex with men compared with other sexual contact exposures because of the potential for mucosal breakdown and rectal bleeding. Similarly, the presence of genital ulcerative disease increases the likelihood of HIV transmission through sexual contact. Among heterosexual contact, the likelihood of HIV transmission is greatest after receptive anal intercourse, followed by receptive vaginal intercourse and insertive vaginal intercourse. Male to female transmission of HIV is more common than female to male transmission. The risk of transmission after the use of injection needles is greater after percutaneous injection of a contaminated needle into an artery or vein. Other important factors influencing the risk of HIV transmission include HIV status and viral load of the source.

The CDC recommends PEP for persons presenting within 72 hours after an exposure to a source known to be HIV-positive if contact of body fluid contaminated with blood (including semen, vaginal secretions, rectal secretions, and breast milk) was made with the vagina, rectum, eye, mouth or other mucous membrane, or nonintact skin or by percutaneous injection. Efforts should be made to determine the current HIV status of the source. HIV status of the individual seeking care should also be obtained.

A three-drug combination therapy is recommended. Because each of these medications has its side effects and toxicities, the decision of which agents to use should be made in conjunction with an infectious disease specialist. The patient should be observed closely so his or her progress can be monitored. PEP should continue for 28 days. Whereas most seroconversions will occur in the first 3 months after the exposure, these patients should be checked for HIV at 6 weeks, 12 weeks, and 6 months. The PEPline is also available to provide advice (see earlier).

**DISPOSITION**

It is important for emergency clinicians to be aware of the available resources for patients who have a high suspicion for HIV or have recently tested positive to ensure appropriate follow-up and further evaluation. The personal and public health consequences of HIV transmission are severe.
of patients who have been lost to follow-up are significant, and a proactive approach for ensuring outpatient care is essential.

The widespread use of ART among HIV-positive individuals has dramatically changed the course of the disease; individuals often have sustained and lasting immune reconstitution and live relatively normal lives. Knowledge of their immune status is critical for disposition and treatment; patients with a normal or near-normal CD4+ count should be treated like non–HIV-infected patients. Drug interactions are common. Patients with AIDS, unlike immunocompetent patients, often suffer from multiple, simultaneous underlying pathologic processes, making evaluation and treatment decisions even more difficult; a unifying diagnosis is not the norm. These patients are at greater risk of morbidity and mortality from common disease entities, as well as from complications of HIV/AIDS. Emergency clinicians who approach these patients with background knowledge of the potential manifestations of HIV/AIDS will be poised to deliver the best emergent care.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
124.3. A 52-year-old male patient presents with 3 days of confusion, fever, and headache. He was diagnosed with HIV 3 weeks ago and is not currently taking antiretroviral medications. His CD4+ count at that time was 32 cells/µL. He has lived in the United States all his life. A head CT scan with contrast on this visit reveals multiple ring-enhancing lesions. Which of the following is the most likely cause of this central nervous system (CNS) lesion?

A. Cytomegalovirus encephalitis
B. HIV encephalopathy
C. Mycobacterium tuberculosis
D. Progressive multifocal leukoencephalopathy
E. Toxoplasma gondii

Answer: E. Toxoplasma encephalitis presents over days to weeks with fever, headache, altered mental status, focal neurologic findings, and/or seizures. In 90% of cases, there are ring-enhancing CNS lesions. The CD4+ count is typically less than 100 cells/µL, and often the count is much lower. The main differential diagnosis in developed countries is CNS lymphoma. Patients with ring-enhancing CNS lesions are often empirically treated for Toxoplasma, and then a repeat CT scan is performed. A brain biopsy is diagnostic. Tuberculoma must be considered in patients with an exposure to tuberculosis and in those who live in areas highly endemic for tuberculosis.

124.4. A 36-year-old woman presents with a warm, red, painful lower leg. She has multiple other dermatologic concerns, including flesh-colored, dome-shaped lesions on her face, a new dark pigmented lesion on her arm, cold sores, and facial erythema. Which of her cutaneous findings suggests HIV disease?

A. Cellulitis
B. Facial molluscum
C. Melanoma
D. Oral herpes
E. Rosacea

Answer: A. All the answers except A are AIDS-defining conditions.
**Answer:** B. HIV has many cutaneous manifestations. In this case, her facial molluscum is highly suggestive of HIV disease.

124.5. A 35-year-old man with AIDS presents with fever and a productive cough for 1 day. His last known CD4+ count 1 month ago was 538 cells/µL. He has a lobar pneumonia in the left lower lobe on his chest radiograph. There is no evidence of lymphadenopathy. What is the most likely culprit pathogen in this case?

A. *Cryptococcus neoformans* pneumonia  
B. Disseminated *Mycobacterium avium* complex  
C. *Pneumocystis jiroveci* pneumonia (PCP)  
D. Pulmonary tuberculosis  
E. *Streptococcus pneumoniae*  

**Answer:** E. It is critical to have an understanding of diseases relative to the absolute CD4+ T cell count. Patients with CD4 counts higher than 500 cells/µL typically develop illnesses similar to the general population. This patient presents with a lobar pneumonia, and *S. pneumoniae* is the most common cause. PCP is the most common opportunistic pathogen in AIDS patients, usually occurring in those with a CD4+ T cell count lower than 200 cells/µL. It would be extremely unusual for PCP to cause a lobar pneumonia in someone who is immune-reconstituted. Tuberculosis can occur at any stage of HIV infection. However, the symptoms tend to be more gradual in onset, and a lobar pneumonia is unlikely.
OVERVIEW

An understanding of parasitology has become increasingly important for physicians practicing emergency medicine. There has been a dramatic increase in immigration from Southeast Asia, Central and South America, and Africa into the United States during the last few decades. Many of these people have emigrated from countries of origin under dire circumstances, fleeing civil unrest, war, famine, economic hardship, political persecution, and environmental devastation; many had lived in regions where parasitic infections were, and continue to be, endemic. Business and adventure travel, including ecotourism, frequently transports immunologically naive and vulnerable hosts to sites rich in parasitic disease. Patients with human immunodeficiency virus (HIV) infection or acquired immunodeficiency syndrome (AIDS) who travel to countries where parasitic illnesses are endemic are at higher risk of contracting these illnesses. Patients with AIDS who immigrate or travel to the United States may harbor a number of devastating parasitic illnesses. There continues to be a significant prevalence of endemic parasitic disease in many rural areas of the southeastern and southwestern United States and, in some parts of Europe, climate change is extending the habitat of what were known as tropical parasites and vectors to previously temperate regions. The growing population of patients with parasitic illness often initially seek treatment for their clinical symptoms in an emergency department (ED).

When parasitic illness is correctly diagnosed and treated promptly with effective chemotherapy, patients generally recover rapidly and completely (Table 125.1); however, parasitic illness often begins insidiously, and delayed treatment or mismanagement of parasitic diseases can be disastrous. Without appropriate treatment, many parasitic diseases will pursue a chronic and relentless course, resulting in damage to the host's end organs, severe morbidity, and even death. To diagnose parasitic infection, the emergency clinician must be vigilant and must obtain a thorough travel history, perform a detailed physical examination, and order appropriate laboratory studies. This information must be integrated with a strong understanding of the basic life cycles of parasites, variations in presentation of infection, intersecting geography of the organism and host, and characteristics of incubation periods between inoculation and clinical presentation.

The incubation period for the development of symptoms for parasitic diseases ranges from days (falciparum malaria) to months (vivax malaria) to years (filariasis). Uncovering parasitic illness depends heavily on Osler’s principle—to make the diagnosis, the clinician must first think of the diagnosis.

Travel History

Parasitic illness should be considered in the differential diagnosis of almost every sign or symptom of illness in patients who recently have spent time in areas of the world with endemic parasitic illnesses (Table 125.2). Accordingly, a travel history should be included in the evaluation of most, if not all, patients presenting to the ED, and should include the questions summarized in Box 125.1. For patients who have recently immigrated to the United States, the emergency clinician should elicit additional information specific to the country of origin, also summarized in Box 125.1.

Therapy

New and more effective antiparasitic agents are continually being developed. The list of drugs used to treat parasitic infestations is large and varied. Table 125.3 includes some of the newest pharmaceutical agents as well as other older medications that are still recommended.

The newer antiparasitic drugs are less toxic and more effective. Parasite biochemical pathways are generally different from those in the human host, permitting selective metabolic interference by using relatively small doses of chemotherapeutic agents. In many cases, single-dose treatment can eradicate an entire parasite burden, leading to implementation of effective mass treatment programs in infected populations in endemic areas. One dose of ivermectin given annually to patients living in endemic areas prevents onchocerciasis. Treatment and disposition in the ED, however, focuses only on the individual patient and particular disease entity.

The evolutionary goal of the successful parasite is to live with and at the expense of the living host; a parasite that kills its host has a significant survival disadvantage. Most parasitic infections (with certain important exceptions, such as falciparum malaria) pursue a chronic course and are not acutely life-threatening. Nevertheless, alterations in host immune function can change the virulence and morbid course of more benign infections. Strongyloidiasis can become fulminantly disseminated in patients receiving immunosuppressive medication after organ transplantation, as treatment for cancer and more serious rheumatologic diseases, or after the initiation of long-term steroid therapy. Because of the subacute or chronic nature of most parasitic infections, the clinician should first make a diagnosis, initiate chemotherapy, and then arrange careful follow-up and repeated laboratory examinations to ensure that the patient is cured. When parasites are not eliminated promptly, repeated doses or alternative drugs may be needed because drug resistance among parasitic organisms is becoming increasingly common. In cases of suspected drug resistance, referral to a travel medicine or infectious disease clinic is indicated. A patient who appears clinically ill or has presumptive falciparum malaria—by symptoms or travel history—will usually require hospitalization for initial diagnosis, treatment, and observation.

PRESENTATIONS

The consideration of parasitic diseases is usually approached by correlating historical features such as exposure and travel history with presenting symptoms that can be associated with a number of illnesses, including parasitic infections. It is therefore useful to approach a patient with risk factors and certain presenting complaints as a possible manifestation of infection—fever, anemia,

### BOX 125.1
Comprehensive Travel History for Evaluation of Parasitic Disease in the Emergency Department

**QUESTIONS FOR ALL PATIENTS**
- What were the exact dates of travel?
- What countries did the patient visit?
- How much time was spent in each country?
- What was the patient doing in the country, and where was he or she living?
- Was the patient a tourist, an adventure traveler, or a worker?
- Did the patient stay in cities or rural villages?
- Was the patient sleeping in hotels or tents?
- Did the patient engage in protected or unprotected sexual intercourse?
- What did the patient eat and drink?
- What were the patient’s activities (eg, swimming in fresh water leads to schistosomiasis)?
- Did the patient receive prophylactic immunizations before travel?
- Did the patient take malaria chemoprophylaxis and comply with the regimen?
- Did the patient use mosquito repellent and netting?
- Does the patient have underlying chronic medical problems?
- What medications does the patient take?
- When did symptoms start, and what has been the chronology of symptoms, particularly fever and diarrhea?

**QUESTIONS FOR PATIENTS WHO ARE RECENT IMMIGRANTS TO THE UNITED STATES**
- When did the patient arrive, and from where?
- What acute and chronic illnesses did the patient have previously while living in the country of origin?
- What treatment did the patient receive there?
- If a refugee or immigrant, what countries did the patient pass through, and what were the living conditions (especially relevant for persons who have lived in numerous refugee camps)?
- What was the season during the patient’s stay or travel in the countries (eg, monsoon vs. dry)?
- What animal exposures and bites has the patient experienced?
- Has the patient had exposure to fresh water in work or recreational activities?

peripheral edema, visual impairment, skin complaints, and symptoms related to the pulmonary, cardiovascular, and gastrointestinal (GI) systems.

Fever

Fever is an important presenting symptom for a number of parasitic diseases. The most prevalent and medically devastating globally is malaria, with its classic history of recurring bouts of shaking chills and drenching sweats.

Malaria

The febrile patient with shaking chills and a time-appropriate history of travel to an endemic region requires evaluation for malaria. *Plasmodium falciparum*, *Plasmodium ovale*, *Plasmodium vivax*, *Plasmodium malariae*, and *Plasmodium knowlesi* are the species responsible for human malaria. More than 41% of the world’s population lives in malaria-endemic areas (eg, parts of Africa, Asia, Oceania, Central America, and South America). The World Health Organization (WHO) has estimated that in 2013 malaria caused 198 million clinical episodes and 500,000 deaths. Most of these deaths would be caused by *P. falciparum*.1 Approximately 1500 cases of malaria are diagnosed yearly in the United States. The female *Anopheles* mosquito is the arthropod vector that transmits malaria after ingesting gametocytes from infected humans. The gametocytes reproduce in the gut of the mosquito; sporozoites are then released from the salivary glands of *Anopheles* into a human host during a blood meal. Sporozoites rapidly penetrate the liver parenchymal cells of their host. The proteozoans, now termed *cryptozoites* or *exoerythrocytic schizonts*, multiply rapidly. Eventual lysis of the hepatic cells results in the release of merozoites into the bloodstream, which invade erythrocytes. In *P. vivax* and *P. ovale* infection, dormant hypnozoites can reside in hepatocytes; recrudescence of infections can occur many months to years later.

After invading red blood cells (RBCs), the merozoites transform into trophozoites, which feed on the hemoglobin in RBCs. Trophozoites mature into schizonts, which divide asexually into additional merozoites. The RBCs undergo lysis, releasing merozoites into the blood. Although some merozoites are destroyed by the host’s immune system, many enter new erythrocytes. After several repetitions of this erythrocytic cycle, the cyclic process changes, and male or female macrogametocytes may develop instead of merozoites. These gametes subsequently complete the reproductive cycle by fusion, which is accomplished sexually within the gut of a new female *Anopheles* mosquito after she has taken a blood meal from an infected host. Most people contract malaria after being bitten by an infected vector mosquito in an endemic region. Other mechanisms of transmission have been reported, including blood transfusions, injection drug use with contaminated syringes, maternal-fetal perinatal transmission, transmission from infected organs after transplantation (worsened by immunosuppression), and so-called airport malaria. This occurs when the infected mosquito is transported from the endemic region and released when the plane arrives, surviving long enough to transmit the parasite to a human host and then dying without establishing itself in its new location.2

Clinical Features. All patients presenting from a region endemic for malaria with a fever or acute illness should be evaluated for the possibility of malaria. Most patients with malaria present with cyclic or irregular fevers. Other signs and symptoms include anemia, headache, nausea, chills, lethargy, abdominal pain, and upper respiratory complaints.3 The important difference between *P. falciparum* and the other malaria species is the capability of *P. falciparum* to cause severe organ system damage and death. RBCs infected with *P. falciparum* are rendered sticky and sludgelike in small arterioles and capillaries, causing ischemia in the host’s metabolically sensitive organs.

The manifestations of acute falciparum infection include cerebral malaria with cerebral edema and encephalopathy,
hypoglycemia (especially in children), metabolic acidosis, severe anemia, which may lead to high output cardiac failure, renal failure, pulmonary edema, disseminated intravascular coagulation, and death. In chronic malaria, increased cellularity from the host’s exuberant immune response may lead to hepatosplenomegaly. Within the liver, parasites and malarial pigment distend the Kupffer cells. Parasitized RBCs also adhere to the sinusoidal system of the spleen, reducing its immunologic effectiveness. Anemia results from acute and chronic hemolysis. Blackwater fever—hemoglobinuria caused by severe hemolysis—may occur in patients with chronic or acute falciparum malaria.

**Diagnostic Testing.** Light microscopic examination of thick and thin blood films remains the gold standard for the diagnosis of malaria. The emergency clinician may have to view several slides and multiple fields to make the diagnosis if the parasite burden is small. Peripheral blood smears are stained with Giemsa or Wright stain and examined with ordinary light microscopy. The diagnosis can be made in a simply equipped laboratory. Even if the parasite is not visualized in the smear, treatment of malaria is indicated if the disease is suspected on clinical grounds. The US Food and Drug Administration (FDA) has approved the use of an antigen-based rapid diagnostic test for screening of patients. The Alere BinaxNOW kit provides qualitative testing for all four species and is available on the Internet for approximately $5 per test. The test is not as sensitive as microscopy, which should still be performed for all patients who have positive antigen test results to determine the species and severity of parasitemia.

**Management.** In the past, chloroquine phosphate was the treatment of choice for acute uncomplicated attacks of malaria. Resistance to chloroquine has been steadily increasing, and the drug is now recommended only in regions of known chloroquine sensitivity—Haiti, Dominican Republic, Central America, and limited regions of the Middle East. For uncomplicated malarial infections in patients from chloroquine-resistant regions, oral quinine is given with doxycycline or clindamycin. Another suitable alternative combination is proguanil-atovaquone. For complicated *P. falciparum* infection (eg, cerebral malaria, involvement of multiple organ systems, inability to tolerate oral medication), intravenous (IV) quinine (not available in IV form in the United States) or quinidine is used. Rapid infusion of IV quinine can cause profound hypoglycemia, as well as hypotension and coma, a neurologic impairment due to high rates of parasite destruction. Patients should not receive IV quinine without cardiac monitoring.

The artemisinin agents are excellent antimalarials and are available as enteral and parenteral preparations. They have a rapid onset of action and are well tolerated. An oral agent known as artmether-lumefantrine (Coartem) is now available for uncomplicated malaria. The other artemisinins are not approved for use in the United States; however, parenteral artesunate is available as an investigational drug for patients who have complicated malaria not responding to quinidine. To obtain this drug, contact the Centers for Disease Control and Prevention (CDC) Malaria Hotline at 770-488-7788 (or, during off hours, at 770-488-7100). Primaquine is used to eliminate the hepatic phases of *P. ovale* and *P. vivax* to prevent recrudescence disease. Primaquine therapy is contraindicated in patients with glucose-6-phosphate dehydrogenase (G6PD) enzyme deficiency because it can precipitate severe hemolysis. Untreated falciparum malaria can lead to coma and death; early treatment reduces morbidity and mortality.

**Babesiosis**

Babesiosis is a malaria-like illness that is becoming increasingly prevalent in the northeastern United States (*Babesia microti*), northwestern United States (*Babesia gibsoni*), and Europe (*Babesia divergens*). Babesiosis is particularly endemic to Long Island, Cape Cod, Martha’s Vineyard, Nantucket, and Block Island and, is suspected, along with ehrlichiosis and Lyme disease, in patients on Cape Cod, Block Island, and Long Island who present with the summer flu. The organism is a protozoan, similar in structure and life cycle to the plasmodia. It is transmitted by the deer tick *Ixodes dammini*, the vector of Lyme disease. Several cases have been attributed to transfusions with infected blood. Patients with babesiosis experience fatigue, anorexia, malaise, and emotional lability, with myalgia, chills, high spiking fevers, sweats, headache, and dark urine. Other manifestations include hepatosplenomegaly, anemia, thrombocytopenia, leukopenia, elevated liver enzyme levels (particularly the transaminases), and signs of hemolysis, with hyperbilirubinemia and decreased haptoglobin. In an otherwise healthy person, the disease may remit spontaneously. In asplenic, older, and immunocompromised patients, especially patients with AIDS and those taking corticosteroids, up to 85% of RBCs may contain organisms.

**Clinical Features.** Clinical syndromes in these patients include massive hemolysis, jaundice, renal failure, disseminated intravascular coagulation, hypotension, and adult respiratory distress syndrome (ARDS). Diagnosis is based on clinical suspicion, multiple thin and thick blood smears (*Babesia* organisms resemble plasmodia in blood smears), and serologic testing (convalescent titers may not be positive for several weeks after infection).

**Management.** The treatment of choice consists of atovaquone plus azithromycin or, for severe illness, quinine plus clindamycin. Patients infected with *B. divergens* tend to be sicker and require more supportive care. Coinfection with *Borrelia burgdorferi*, the agent of Lyme disease, results in more severe and prolonged illness.

**Other Parasites**

Other parasitic illnesses that commonly cause significant fever include schistosomiasis, fascioliasis, African and American trypanosomiasis, leishmaniasis, toxoplasmosis, and amebic liver abscess.

Katayama fever may be the initial phase of schistosomiasis. Infected patients report brief exposures to fresh water in endemic areas. Clinical manifestations include spiking fevers, diaphoresis, wheezing, and cough. Fosinopril is common.

Fascioliasis, caused by the liver fluke *Fasciola hepatica*, is endemic throughout all the continents except Antarctica and is found in over 50 countries, especially where sheep or cattle are reared. Infection begins with ingestion of the metacercariae often found in watercress. Within 6 weeks, patients exhibit right upper quadrant abdominal pain, fever, and eosinophilia.

American trypanosomiasis (Chagas’ disease) is endemic to Central and South America. The vector, the reduvid bug, sheds trypomastigotes in its feces proximal to the bite site. The host responds to local inflammation and infection by excoriating the site, inoculating the wound with trypomastigotes and initiating systemic spread. Acute Chagas’ disease begins with a chagoma, an infected and swollen bite site, often periorbital, and quickly progresses to fever, malaise, facial swelling, and pedal edema. Parasitization of cardiac muscle leads to the dysrhythmias and ventricular dysfunction that are classically found in late disease (chronic Chagas’ cardiomyopathy).

Leishmaniasis is spread to humans by the sandfly and is found in the Middle East, India, East Africa, Brazil, and along the Mediterranean coast. Although leishmaniasis can involve the skin (cutaneous) and mucosa (mucosal), fever is seen only in visceral
leishmaniasis in immunocompetent persons. Signs and symptoms also include massive hepatosplenomegaly, neutropenia, and weight loss.16

The patient who has amebic liver abscesses from Entamoeba histolytica infection presents with high fevers, right upper quadrant pain, and elevated white blood cell count.17

**Neurologic Symptoms**

Headache, altered mental status, and seizures are common presenting symptoms of parasitic infections caused by organisms that are neurotrophic. Some of the most common are malaria, cysticercosis, echinococcosis, and trypanosomiasis.

**Cerebral Malaria**

Cerebral malaria is a common, life-threatening complication of *P. falciparum* infection. Parasitized RBCs express malarial cell surface glycoproteins called knobs that are sticky. They adhere to capillary walls, causing sludging in the cerebral microvasculature, localized ischemia, capillary leak, and petechial hemorrhages.

**Clinical Features.** Clinical manifestations include fever, altered mentation, including obtundation, coma, and occasionally seizures. A careful history and early diagnosis and therapy are essential to prevent severe morbidity and death.

**Management.** Treatment of cerebral malaria consists of IV quinine, quinidine, or artemisinin (if available), supportive care, including mechanical ventilation for comatose patients and patients with noncardiogenic pulmonary edema, antiepileptics, and correction of acidosis and hypoglycemia, associated with quinine use and cerebral malaria. The mortality rate is high, especially in children but, if the patient recovers, neurologic sequelae are rare. Corticosteroids, including dexamethasone, provide no benefit and can worsen outcomes in those with cerebral malaria.

**Cysticercosis**

Cysticercosis is caused by the larval form of *Taenia solium*, a common central nervous system (CNS) pathogen in many tropical areas. Cysticercosis is acquired by humans when they eat undercooked pork containing the larval cysts. The adult worm matures in the small intestine; the larval forms may penetrate through the gut wall and end up anywhere in the body. They are neurotrophic for the CNS, muscle, and soft tissue.

**Clinical Features.** In the brain, clusters of larvae of *T. solium* form an expanding cyst that induces an intense immunologic reaction from the host, including inflammation, fibrosis and, ultimately, calcification. Neurologic abnormalities develop when neural tissue cannot accommodate the enlarging cyst. Seizure activity is often the first indication of cysticercosis, which should be considered in the differential diagnosis of new-onset seizures in adults. The diagnosis of *T. solium* infection is established by the finding of characteristic proglottids (gravid segments) or scolices (worm heads) in stool preparations.

**Diagnostic Strategies and Management.** Cranial computed tomography (CT) with contrast enhancement or magnetic resonance imaging may reveal an enhancing ring lesion. These lesions can mimic a CNS abscess, metastatic malignant disease, or primary tumor such as glioblastoma multiforme. Albendazole is the therapeutic agent of choice, and corticosteroids and antiepileptics are important adjunct medications during therapy, because CNS cysts can release highly antigenic inflammatory material at the time of treatment.12,13 Neurosurgical consultation is warranted because neurocysticercosis is commonly associated with acute obstructive hydrocephalus.

**Echinococcosis**

**Principles and Clinical Features.** *Echinococcus granulosus* is another tapeworm capable of causing CNS disease. Cerebral hydatid cysts are loculated structures containing CNS disease. Cerebral hydatid cysts are loculated structures containing *E. granulosus* scolices (heads) and the remains of the germinal epithelium, termed hydatid sand. Common types of exposure include ingestion of food or water contaminated by the ova from feces of sheep or cattle infected by the adult worm and close contact with an infected sheep-herding dog that is shedding ova. Infection results in the liberation of the embryo oncosphere into the small intestine. After penetrating the intestinal wall, the larvae travel through the bloodstream to multiple sites for encystment. The liver is the target organ in nearly two-thirds of cases, but 7% of patients have brain involvement; infected patients may present with seizures or focal neurologic signs.

**Diagnostic Strategies and Management.** The diagnosis of hydatid cyst disease is suggested by the appearance and localization of the cyst on ultrasound examination or CT scan. Serologic evaluation of serum or cerebrospinal fluid (CSF) may help confirm the diagnosis. Aspiration of the cyst should not be attempted because of the risk of seeding the host’s body with metastatic cysts. Treatment options include albendazole and surgical resection. Resection of the cyst may cause an anaphylactoid reaction if there is spillage of hydatid sand, which contains parasite antigenic proteins (Figs. 125.1 and 125.2).14
African Trypanosomiasis

African sleeping sickness is caused by *Trypanosoma brucei gambiense* and *Trypanosoma brucei rhodesiense*. This infection is endemic in limited areas of West and East Africa. Several recent cases have been reported in travelers who have returned from safari in East Africa. The motile organisms are transmitted by the bite of the Glossina (tsetse) fly, which introduces the infective form of the trypanosome into the host’s blood. A small lesion or boil may develop and persist for several days. The flagellated organism travels throughout the bloodstream, invading the lymph nodes and spleen.

**Clinical Features.** Winterbottom’s sign, which is posterior cervical lymphadenopathy, usually is apparent at the time of initial treatment. The patient generally is febrile, and a maculopapular rash can be seen in fair-skinned people. Once the parasite invades the CNS, cerebral inflammation causes severe headache. Patients may display a change of mental status, psychiatric symptoms, and eventually extreme sleepiness and lethargy. Coma and death from starvation and trypanotoxins are inevitable in untreated patients.\(^{15}\)

**Diagnostic Strategies and Management.** An appropriate exposure history and characteristic symptoms should prompt the clinician to obtain diagnostic studies. Trypanosomes in peripheral blood, CSF, or lymph node and bone marrow aspirates establish the diagnosis. The presence of parasites in the CSF indicates advanced progression of the disease. Suramin sodium is the treatment of choice for early infection with *T. b. rhodesiense*. Pentamidine isethionate is the preferred treatment for early *T. b. gambiense* infection. Melarsoprol is used in CNS disease from *T. b. rhodesiense*; eflornithine is used in CNS disease from *T. b. gambiense* infection.

**Strongyloides stercoralis** infection is a common disease in the tropics. The worm enters through the skin and migrates to the small bowel. Infection with *Strongyloides* is more clinically significant in immunosuppressed patients, who may suffer larval dissemination, with subsequent encephalitis and pyogenic meningitis. *Strongyloides* infection is treated with thiabendazole or albendazole. Ivermectin has recently been found to be as effective, with fewer side effects.\(^{16}\)

Granulomas may occur in the brain from egg deposition by *Schistosoma*. In general, they do not cause major symptoms; however, several cases of transverse myelitis with paraplegia have been reported when the immunogenic and inflammatory eggs lodged in the spinal cord of infected patients.

**Anemia**

Anemia in the traveler may reflect hemolysis from malaria, intestinal bleeding from hookworm or whipworm, or nutritional deficiency from tapeworm. These organisms have a profound effect on populations where the disease is endemic, but can also cause symptoms in travelers.

**Malaria**

Malaria infection often is associated with anemia, especially in children younger than 5 years (Fig. 125.3). Anemia may develop quickly, from massive hemolysis in acute infection, or may have a more insidious onset, developing over months. Mature merozoites lyse parasitized RBCs. Uninfected RBCs undergo immune destruction from cell surface antibodies produced in response to parasite-associated changes in RBC surface proteins. This process of destruction is abetted by increased reticuloendothelial activity. The reticulocyte response in infected persons is blunted by the inhibition of erythropoietin secretion. The antimalarial drug primaquine can precipitate hemolysis in patients who have G6PD deficiency, which is common in many Africans and some Asians.

---

**Fig. 125.3.** Severe life-threatening anemia (hematocrit of 9) in a 5-year-old child in association with chronic malaria.
Whipworm and Hookworm

Infestation by the whipworm *Trichuris trichiura*, and especially by the two human hookworms *Necator americanus* and *Ancylostoma duodenale*, is a major cause of iron deficiency anemia worldwide. Adult worms penetrate into intestinal mucosa and feed, causing significant luminal blood loss. The host’s feces contain eggs that mature in the soil through a rhabditiform larval form to the infective filariform larva. These larvae penetrate the human skin, usually through the feet. In trichuriasis, anemia is seen only with massive parasite infestation. Ova from the whipworm are ingested through food and water contaminated with feces. Diagnosis of these infections requires identification of characteristic ova in the stool. As with most helminthic infections, peripheral eosinophilia is common; prevention of superinfection requires a meticulous skin care.

Praziquantel is the drug of choice for adults and children.**20** The drug is made by identification of the ova in the feces. Praziquantel is effective in the treatment of *Diphyllobothrium latum*, a tapeworm that develops in the human small intestine. The diagnosis of *D. latum* takes place when the host ingests raw freshwater fish that contains the adult tapeworm. Subsequent mechanical blockage of the lymphatic system leads inevitably to severe lower extremity and genital edema that accompanies thickening of the skin. Recurrent cellulitis is common in these patients; prevention of superinfection requires meticulous skin care.

Tapeworm

Infection with the fish tapeworm *Diphyllobothrium latum* is associated with pernicious anemia. This tapeworm competes with the human host, absorbing vitamin B₁₂ from the host’s intestine. When the host ingests raw freshwater fish that contains the embryo plerocercoid larvae in its muscle fibers, the large adult tapeworm develops in the human small intestine. The diagnosis is made by identification of the ova in the feces. Praziquantel is the drug of choice for adults and children.**20**

Peripheral Edema

Lymphedema is classically associated with filarial infection, although it can also be associated with parasite-induced malnutrition and hypoproteinemia.

Elephantiasis

Elephantiasis, or filariasis, is manifested in the host by the development of massive peripheral edema, with distention and thickening of the overlying epidermis, which acquires the appearance and texture of elephant skin. Elephantiasis is caused by infection with the filarial worm *Wuchereria bancrofti* or *Brugia malayi*. The infection is confined to humans and is widely distributed in the equatorial regions of the world, including Africa, Asia, South America, and Oceania. More than 90% of all infections are found in tropical regions of the world, including Africa, Asia, South America, and Oceania. More than 90% of all infections are found in endemic regions in which most residents are infected, but can be seen in the United States in tourists returning from the Caribbean, Central, and South America. Elephantiasis is a major cause of iron deficiency anemia worldwide.

Diagnostic Strategies and Management. The adult female worm produces microfilariae, which reach the peripheral blood through the lymphatics, whereupon the patient experiences shaking chills and fever. Thick peripheral blood smears may show infection, particularly at night, when the release of microfilariae is most common. Diethylcarbamazine rapidly clears the microfilariae from the peripheral blood and slowly sterilizes the gravid female nematode. Combined therapy with diethylcarbamazine and albendazole, or ivermectin and albendazole, may be more effective.**21** Established elephantiasis of the scrotum can be successfully treated surgically. Chronic lymphatic obstruction of the limbs rarely responds to operative intervention.

Dermatologic Symptoms

Dermatologic symptoms reflecting parasitic infection are more likely to be encountered by physicians working in countries where the organisms are endemic, but can be seen in the United States in tourists returning from the Caribbean, Central, and South America.

Cutaneous Leishmaniasis

Cutaneous leishmaniasis is one of the most important causes of painless, chronic, ulcerating skin lesions in the world. *Leishmania braziliensis* and *Leishmania mexicana* are responsible for New World leishmaniasis; *Leishmania tropica* and *Leishmania major* commonly cause Old World leishmaniasis. The female *Phlebotomus* sandfly transmits the promastigotes during a blood meal, which are ingested by host macrophages and survive in their leishmanial form in the skin.

Clinical Features. Skin papules and nodules are seen early in the course of infection at the site of the insect bite. A raised macule also can appear, which subsequently develops painless central ulceration and a raised border. Lymphocyte and macrophage invasions of the epidermis and dermis cause the induration that occurs at the ulcer border. Secondary bacterial infections of these ulcers increase the associated scarring. *L. braziliensis braziliensis* (subspecies of *L. braziliensis*) attacks the mucocutaneous skin borders (ie, in tissues of the nose and mouth). Mutilation of the face occurs after massive tissue and nasal cartilage destruction. The larynx and trachea also can be involved, compromising the airway. Disseminated cutaneous leishmaniasis (*L. mexicana amazonensis* in South America and *L. tropica aethiopica* in Ethiopia) is characterized by diffuse nodules and papules resembling those of lepromatous leprosy (Fig. 125.4). Persons with this manifesta-

**Fig. 125.4.** Cutaneous leishmaniasis.
tion of leishmaniasis are thought to have a defect in their cell-mediated immunity response.

**Diagnostic Strategies and Management.** Definitive diagnosis of leishmaniasis is made by direct visualization of the parasite with light microscopy. Diagnosis can also be made by an indirect fluorescent antibody test. Results of intradermal skin testing often are negative during the acute stages of the disease. Many forms of cutaneous leishmaniasis, especially *L. tropica* and *L. mexicana* infection, are self-limited and require no treatment unless the wounds become secondarily infected. Treatment options for advanced disease include sodium stibogluconate, meglumine antimoniate, and amphotericin B. In 2014, the FDA approved the first oral medication, miltefosine, which can be used to treat leishmaniasis. These treatments are rarely initiated in the ED setting.

**Dracunculiasis**

**Principles and Clinical Features.** *Dracunculus medinensis*, the fiery serpent, is also referred to commonly as guinea worm disease (GWD). GWD appears in the host as the adult worm migrates through the subcutaneous tissues of the leg. The head of the gravid adult female eases through the skin of the leg and releases larvae into the water when the host wades in a pond or open well. The larvae promptly infect the *Cyclops* water flea. Humans who drink water containing the infected crustacean complete the cycle of infection. The patient may complain of rash, intense pruritus, nausea, vomiting, dyspnea, and diarrhea before the female worm erupts through the skin.

**Management.** The classic treatment in developing countries has been to wind the worm around a stick and slowly extract the parasite from the skin during the course of 1 or 2 days. If the worm breaks while it is being extracted, the patient experiences an intense inflammatory reaction, with cellulitis along the worm track. The diagnosis is confirmed when microscopic larvae are found in the fluid of the cutaneous ulcer or when the adult female worm is identified extruding from the skin. The use of metronidazole to shorten the time of extraction is controversial. WHO has set a goal to eradicate this disease through public health awareness—encouraging the covering of wells, filtering well water to remove the fleas, and keeping infected persons with active skin lesions out of potable water. These efforts have had a tremendous impact on the eradication of dracunculiasis from Africa.31

**Other Parasites**

Cutaneous larva migrans, the creeping eruption, occurs in the host’s epidermis when the skin is penetrated by *Ancylostoma braziliense* (dog or cat hookworm) larvae. Exposure usually occurs after walking barefoot or lying on beaches or other warm soil contaminated by animal feces. The diagnosis is suggested by the presence of a characteristic meandering erythematous track on the skin surface caused by larval migration. Visceral larva migrans occurs in young children after the ingestion of soil containing ova from the dog ascarid *Toxocara canis*. Thiabendazole, ivermectin, or albendazole may be used for treatment of cutaneous larva migrans, and antipruritics give symptomatic relief. Diethylcarbamazine treats visceral larva migrans. An alternative is thiabendazole.24

Swimmer’s itch is a dermatitis that occurs when skin is penetrated by the nonhuman schistosome of avians and mammals, usually from swimming in northern US freshwater lakes. The infection spontaneously resolves when the nonhuman schistosome is destroyed by the human host’s immune system. A similar dermatitis also can occur after infection with schistosome species that are trophic for humans. Treatment is symptomatic. *Strongyloides* can cause a transient pruritic rash that may appear and then disappear within hours. *Taenia solium* can cause cysts in the soft tissues and muscles. These cysts often are an incidental finding. Onchocerciasis (from *Onchocerca volvulus*), which is common in West Africa and parts of South America, can cause severe pruritus and the development of nodules on bony protuberances.

**Visual Symptoms**

**Onchocerciasis**

Onchocerciasis is a major cause of blindness in the world. Of all cases, 95% occur in Africa. The parasite is found only in humans and is transmitted by the bite of the *Simulium* fly. These flies live near rivers—hence, the common name of the disease, river blindness. Microfilariae of *O. volvulus* are released by adult nematodes, which coil in subcutaneous nodules in the infected host; the microfilariae then migrate through the dermis and epidermis. The presence of adult worms stimulates a brisk immune response, including the infiltration of lymphocytes, macrophages, plasma cells, and eosinophils.

**Clinical Features.** The skin becomes chronically edematous and pruritic; it then atrophies, resulting in loose thin folds of skin. River blindness is more likely to develop in patients with nodules in proximity to the eyes. When the microfilaria dies during its migration in the eye, the foreign tissue that is deposited in the iris musculature incites an immune sclerosing keratitis, which is the major cause of the ocular destruction and subsequent blindness (Fig. 125.5).

**Diagnostic Strategies and Management.** The diagnosis of onchocerciasis requires the identification of characteristic microfilariae in skin snipped from the patient. Ivermectin is the therapeutic drug of choice. In many countries in which the disease is endemic, the manufacturers of ivermectin have donated the drug in an attempt to eradicate the disease.25 Surgical excision of the subcutaneous nodules is recommended when they are located on the head.

**Loiasis**

**Clinical Features.** Another filarial infection that causes ocular problems is loiasis. Loiasis is confined to forest areas in West and Central Africa. Transmission of *Loa loa* occurs through
the bite of flies of the genus *Chrysops*. The edema initially associated with migration of the worm is called a Calabar swelling. The disease is caused by migration of the adult worm in the subcutaneous tissue. The adult worm occasionally migrates through the subconjunctival tissue of the eye and can be surgically excised from the conjunctiva. Although it is upsetting to the patient, the disease is generally fairly benign. The adult worm releases sheathed microfilariae into the peripheral bloodstream during the daytime.

**Diagnostic Strategies and Management.** Microfilariae can be detected in a thick blood smear, securing the diagnosis of loiasis. The treatment of choice for *L. loa* infection is diethylcarbamazine. Corticosteroids or antihistamines should be used to supplement specific chemotherapy because of the intense allergic reaction that occurs when the killed adult worms and microfilariae disintegrate.

**Other Parasites**

*Toxocara canis* (dog roundworm) has a trophism for the host’s eyes. Toxocariasis is a roundworm infection found in urban dogs. Humans ingest eggs by the fecal-oral route. The larvae migrate and often enter the retina, where they become trapped. They stimulate an immune response that culminates in granuloma formation. These granulomas can impair vision and sometimes are mistaken for retinal tumors. There is no means of direct diagnosis except tissue biopsy. Although serologic tests are available, results need to be interpreted with caution. Infection is treated with albendazole and steroids; larvae visible in the retina can be destroyed with a laser.

*Toxoplasma gondii* infection can precipitate a vitreal inflammation with retinal hemorrhages. Immunocompromised patients may have chorioretinitis and optic neuritis, with visual field defects and ocular palsy. Erythrocytes with sticky knobs from *P. falciparum* infection can cause retinal vascular congestion and ischemia with hemorrhage, exudate, infarction, and macular destruction. Cerebral malaria can produce cortical blindness. Ischemia with hemorrhage, exudate, infarction, and macular damage in lung biopsy material. Untreated infection may result in obstructive or restrictive lung disease. Patients have marked eosinophilia and elevations of serum immunoglobulin E levels.

*Paragonimus westermani* and echinococcal species are trophic for the lungs in their human hosts. *P. westermani* eggs are shed in stool, hatch in fresh water and, as miracidia, infect a snail intermediate host. After further development, cercariae are released from the snail, penetrating and encysting in freshwater crabs or crayfish. If the human host consumes raw or undercooked shellfish, the metacercariae excyst within the host’s duodenum, penetrating the duodenal wall into the abdominal cavity. The larvae migrate from the peritoneal cavity through the diaphragm into the pleural cavity, finally migrating to the lungs, where they cause hemorrhage, necrosis, and a granulomatous response. Early in the process, patients may have infiltrates and eosinophilia; later disease is marked by bronchiectasis, chronic bronchitis, fever, hemoptysis, and cachexia. Pulmonary nodules and cysts may cavitate. Many of these patients may have a positive result on purified protein derivative (PPD) testing, and their symptoms and chest radiographic findings may mimic those of tuberculosis. Sputum often is blood-streaked and flecked with dark brown particles containing ova. Finding of ova in sputum is diagnostic. Radiography, stool examination, and immune testing of sputum and blood are all helpful in making the diagnosis. Praziquantel is the therapeutic agent of choice.

*E. granulosus* causes pulmonary hydatid cyst disease; the host remains asymptomatic until a cyst grows large enough to cause a mass effect, becomes superinfected, or leaks cyst material, which is highly immunogenic and causes a severe anaphylactoid reaction. Pulmonary hydatid cysts also can be associated with cough, expectoration of sandlike material, chest pain, and hemoptysis. Primary hydatid disease in the liver can metastasize to the lungs or brain. A thoracic CT scan may show a unilocular lung cyst; on a plain radiograph, a ruptured cyst is said to resemble a water lily, a pathognomonic finding. Cysts can be treated with careful surgical excision and pharmacotherapy.

Early schistosomal disease, or Katayama fever, manifests with fever, cough, eosinophilia, and diffuse pulmonary nodules as the respiratory opportunistic infections seen in patients with HIV infection in the United States and Europe; surprisingly, however, it is responsible for less than 10% of pulmonary opportunistic infections in Africa and the developing world. The reason for this discrepancy is unclear. Many patients with AIDS in these countries die with CD4+ cell counts higher than those associated with *P. jiroveci* pneumonia in the United States.26

Loeffler’s syndrome, characterized by persistent and nonproductive cough, subternal chest pain, wheezing, rales, pulmonary infiltrates on the chest radiograph, and marked eosinophilia, often is seen when larvae from the roundworm *Ascaris lumbricoides*, the hookworms *N. americanus* and *A. duodenale*, and the threadworm *S. stercoralis* transit the lungs as part of their developmental cycles. *Ascaris* larvae penetrate the small intestinal wall to gain entry into the small venules of the GI tract and then migrate to the lungs. *Strongyloides* and the hookworm *filariform* larvae penetrate through the skin of the feet, entering small cutaneous venules before migrating to the lungs. The pulmonary infiltrates and symptoms are transient, resolving within 2 weeks. Diagnosis depends on the discovery of larvae in sputum or gastric aspirates. Negative stool examinations initially are nondiagnostic because eggs do not appear in the stool for at least 1 month after initial infection.

The patient’s immune response to the microfilariae of *W. bancrofti* and *B. malayi* is the cause of tropical eosinophilic pneumonia. Affected persons present with malaise, weight loss, new-onset nocturnal wheezing and asthma, shortness of breath, and chest discomfort. Chest radiographs may show nodular or interstitial infiltrates, consolidations, or cavitation. Microfilariae can be seen in lung biopsy material. Untreated infection may result in obstructive or restrictive lung disease. Patients have marked eosinophilia and elevations of serum immunoglobulin E levels.

**Pulmonary Symptoms**

A number of parasitic infections may be associated with pulmonary symptoms, although the presence of pulmonary findings may not be sufficient to differentiate between various forms of parasitic diseases. Patients with *P. falciparum* malaria initially may seek treatment for fever and cough, further necessitating the consideration of malaria in travelers with apparent respiratory symptoms. Early in the course of treatment for severe malaria, noncardiogenic pulmonary edema or ARDS may develop, necessitating mechanical ventilation with positive end-expiratory pressure.

*E. histolytica* can cause sympathetic pleural effusions, pulmonary or pleural involvement by direct extension or rupture of an amebic liver abscess, or direct hematogenous seeding of the lungs, leading to considerable additional morbidity and mortality among patients with underlying amebic infection.

*Pneumocystis* pneumonia, caused by *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*), is one of the most common diseases in Africa and the developing world. The reason for this discrepancy is unclear. Many patients with AIDS in these countries die with CD4+ cell counts higher than those associated with *P. jiroveci* pneumonia in the United States.26
Schistosomula pass through the lungs. In long-standing disease, ova shed from worm pairs can lodge in the vasculature of the lungs, causing pseudotubercles, granulomatous lung disease, pulmonic hypertension, and cor pulmonale. In patients with long-standing, latent, and asymptomatic S. stercoralis infections who are started on corticosteroids or immunosuppressive therapy, the helminth disseminates widely. Fatal, massive pulmonary infections with radiographic whiteouts and unsupportable respiratory failure have been reported in patients who have received organ transplants; this clinical disaster usually occurs in patients who emigrate from developing countries and receive organ transplants and immunosuppressive therapy without being evaluated for Strongyloides infection.\(^{29}\) Strongyloides pulmonary infection can cause wheezing and cough, leading to an initial misdiagnosis of bronchospasm and asthma. If the patient is given steroids, the strongyloides may disseminate, with markedly increased morbidity and mortality.\(^{29}\)

### Cardiovascular Symptoms

**Chagas’ Disease**

*Trypanosoma cruzi* infection often leads to acute and chronic myocarditis. *T. cruzi* is endemic in South and Central America and causes Chagas’ disease. The vector is the reduviid bug (kissing bug) that inhabits the walls and roofs of thatched dwellings built adjacent to a forest. Urban transmigration has expanded the epidemiologic scope of Chagas’ disease, previously a disease of rural populations. The disease is not seen commonly in travelers. The reduviid bug’s bite is no longer the only source of *T. cruzi* infection; transfusion with blood containing live trypanosomes from infected hosts has been a growing source of infection. Oral transmission also has been reported.\(^{33}\)

The reduviid bug bites the patient, often around the eye, and excretes feces containing the trypomastigote of *T. cruzi*. The trypomastigote enters the inflamed bite wound or other mucosal or conjunctival surfaces, causing a local swelling called a chagoma. Románia’s sign (painless unilateral peri orbital edema) is pathognomonic but rarely seen. The trypomastigote migrates to trophic tissues, including smooth muscle, cardiac muscle, and autonomic ganglia in the heart, esophagus, and colon, causing local inflammation and tissue destruction.

**Clinical Features.** Acute infection is heralded by fever, facial and dependent extremity edema, hepatosplenomegaly, lymphadenopathy, malaise, lymphocytosis on peripheral blood smear, and elevated liver transaminase levels. At this stage, fatal left ventricular dysfunction and dysrhythmias are uncommon. Early illness lasts 1 to 2 months and resolves spontaneously, resulting in a latency known as the indeterminate phase, which can persist throughout the patient’s lifetime. In approximately 25% of cases, the infection progresses to chronic Chagas’ disease, principally with cardiomyopathy and GI pathology. Amastigotes invade cardiac muscle and the cardiac conduction system, causing chronic inflammation, mononuclear cell infiltration, and fibrosis. Patients whose disease involves the conduction system may present with atrial brady dysrhythmias, right and left bundle branch blocks, complete heart block, and ventricular dysrhythmias, including ventricular fibrillation. Cardiac muscle is replaced by fibrosis and scarring, leading to the development of right and left ventricular dysfunction and dilated cardiomyopathy. Mural thrombi are common. The first indication of long-standing asymptomatic infection can be thromboembolic disease, such as pulmonary embolism, stroke, or peripheral arterial embolism. Congestive heart failure is generally rapidly progressive and fatal within months unless treated with pharmacologic intervention and transplantation.\(^{28}\)

**Diagnostic Strategies.** Acute Chagas’ disease can be diagnosed by the presence of motile trypomastigotes in anticoccagulated blood specimens. The organism also can be cultured in special liquid media. Chronic Chagas’ disease can be diagnosed by one of several serologic tests, including complement fixation, enzyme-linked immunosorbent assay (ELISA), and indirect immunofluorescence testing. The assays are nonspecific, cross-reacting with malaria, syphilis, leishmaniasis, and some collagen vascular diseases. Polymerase chain reaction (PCR) technology has been improving and soon will provide the gold standard modality for diagnosis.\(^{30}\)

**Management.** Nifurtimox and benznidazole are used for treatment of *T. cruzi* infection. Cure rates rarely exceed 50%. The duration of treatment with nifurtimox is prolonged, and the drug has many serious side effects. Its production has been discontinued; however, it is the only antityrpanosomal medication available in the United States today (it can be obtained from the CDC by calling 404-639-2888). Benznidazole has fewer side effects. It is now recommended for indeterminate-phase treatment. Late complications of chronic diseases are modulated by autoimmune activity and do not respond to antiparasitic pharmacotherapy. Chronic Chagas’ disease of the heart, esophagus, or colon is treated symptomatically. Automated implantable cardioverter-defibrillators decrease the incidence of sudden death in infected patients.\(^{31}\) Patients receiving immunosuppressive therapy to prevent rejection after cardiac transplantation have developed recurrent disease in the transplanted myocardium.

### Other Parasites

**Diarrhea**

Diarrhea is one of the most common symptoms for which travelers seek medical attention. Gorbach wrote that “Travel expands the mind and loosens the bowels.”\(^{32}\) Diarrhea also is the leading cause of death in children younger than 5 years in developing countries and a major source of morbidity for older children and adults. Most diarrheal disease is viral or bacterial; however, some clinically significant diarrheal disease is caused by parasites. *Cryptosporidium parvum* and *Cyclospora cayetanensis* are foodborne and waterborne coccidians that cause watery diarrhea. Both are particularly significant causes of morbidity in malnourished children and patients with AIDS. Cryptosporidial oocysts can be seen in stool when an acid-fast stain is used. ELISA and immunofluorescent assays of stool also are available for this organism. Paromomycin decreases diarrheal frequency in patients with AIDS who have cryptosporidial infections, who would have prolonged disabling symptoms without treatment. *Cyclospora* oocysts can be detected in stool samples with a Ziehl-Neelsen stain. Trimethoprim-sulfamethoxazole treats this infection.\(^{33}\)

*E. histolytica* causes an invasive or inflammatory diarrhea. Patients complain of fever, tenesmus, abdominal pain, and watery stool containing blood and mucus. Untreated disease can progress to widespread colitis and perforation of the bowel wall, with peritonitis and death. Stool examination reveals mobile trophozoites containing ingested RBCs. Cysts noted on stool studies do not necessarily reflect active infection because there are nonpathogenic ameba species that can be found in the bowel of healthy adults. Immune assays of stool can now differentiate between *E.*
Several parasites have been identified in the pathologic examination of appendices of patients diagnosed with tropical appendicitis. These infections have included enterobiasis, amebiasis, ascariasis, trichuriasis, and taeniasis.

**Abdominal Pain**

Several parasites have been identified in the pathologic examination of appendices of patients diagnosed with tropical appendicitis. These infections have included enterobiasis, amebiasis, ascariasis, trichuriasis, and taeniasis.

\( S. \) *stercoralis, Capillaria philippinensis, T. trichiura, and Schistosoma* have been associated with diarrhea. Hyperinfection or dissemination of *Strongyloides* can cause persistent diarrhea, weight loss, and abdominal pain. *Trichuris* causes diarrhea when the parasite load in the intestine is high. Schistosomiasis can cause a chronic granulomatous colitis, which may resemble inflammatory bowel disease, or an acute, bloody, febrile colitis associated with Katayama fever in the immunologically naïve patient.

In chronic schistosomiasis, worm pairs in patients’ mesenteric and portal venous systems lay eggs that become ensnared in the liver, causing intense local inflammation, scarring, and the classic pipestem cirrhosis, with portal fibrosis. Clinical manifestations in these patients include portal hypertension, ascites, and esophageal varices (Figs. 125.6 and 125.7). Upper GI bleeding is not as common as in patients with alcoholic cirrhosis; however, a large number of patients are infected with schistosomiasis in endemic regions, so variceal bleeding is an important cause of GI hemorrhage in these populations.

\( A. \) *lumbricoides* (roundworm) can cause significant persistent or recurrent abdominal pain in adults and partial intestinal obstruction in children with significant worm loads. Anthelmintics and conservative supportive therapy usually eliminate the problem, thereby avoiding surgical intervention. Clinicians diagnose ascariasis by identifying eggs in the stool. Patients with large worm loads may excrete adult worms, especially after therapy is started. Severe intestinal amebiasis can be complicated by colonic perforation and peritonitis.

*Angiostrongylus costaricensis*, a nematode known as the rat lung worm, is common in Central America. Infected children may appear clinically to have Meckel’s diverticulum or acute appendicitis. Manifestations of the infection include nausea, vomiting, fever, abdominal pain localized to the right lower quadrant, and a tender mass. Surgical exploration may uncover abscesses, obstruction, or intestinal infarction. Anisakiasis is characterized by severe abdominal pain after the ingestion of raw fish (sushi and sashimi primarily). *Anisakis marina*, a nematode that burrows into the intestine, is the pathogen.

The liver fluke *Fasciola hepatica* causes a syndrome that mimics that of viral hepatitis—right upper quadrant pain, fever, nausea and vomiting, jaundice, tender enlarged liver, and elevated transaminase levels. Patients also have eosinophilia and urticaria. Imaging studies, including CT, show the tracks of burrowing flukes. Serologic testing establishes the diagnosis; the patient’s stool may not contain eggs for several months after ingestion. Eggs of schistosomes become trapped in the portal venules, where they trigger an inflammatory response, leading to granulomatous liver disease, fibrosis, and cirrhosis. Hepatic granulomas also are seen in disseminated strongyloidiasis and aberrant biliary ascariasis.

*E. histolytica* can cause hepatic abscesses. Affected patients typically do not have amebic dysentery and do not shed *Entamoeba* in their stool, but results of serologic studies are almost always positive. Patients have fever, weight loss, anorexia, and right-sided abdominal pain, but no jaundice. These patients are
treated with metronidazole or tinidazole and a luminal amebicide, such as iodoquinol. E. granulosus produces hydatid cysts of the liver that on CT contain septations and so-called daughter cysts. Pharmacotherapy with albendazole and careful excision remain the treatments of choice. Leaking cyst material can initiate a severe anaphylactoid reaction in the host.

Jaundice may result from hemolysis secondary to direct infection of RBCs with Plasmodium or Babesia or from biliary obstruction with pigmented stones. Ascaris can cause biliary colic, pyogenic cholangitis, pancreatitis, or liver abscess. Dead worms can be the nidus for gallstone formation. Biliary imaging and endoscopic retrograde cholangiopancreatography will show worms in the biliary tree. Mechanical removal by endoscopy combined with anthelmintic therapy is curative. Clonorchis sinensis and F. hepatica are trophic for the biliary tree. These worms can be present without producing symptoms for years before eventually precipitating cholecystitis, cholangitis, or cholangiocarcinoma.

**Pruritus Ani**

Enterobius vermicularis, or pinworm, causes pruritus ani, a syndrome of intense perianal itch occurring primarily in children. Autoinfection is common because children (and adults) scratch the pruritic anal area and then bite their nails or put their fingers in their mouth. The worm has a worldwide distribution. Diagnosis is clinical and is confirmed by finding the small adult worms wiggling about on the anal verge. Eggs are rarely seen in the stool but can be visualized by the tape test—transparent tape touched to the perianal region collects eggs, which can be seen with light microscopy. Albendazole or mebendazole is the drug of choice.

**PARASITIC CO-INFECTIONS IN PATIENTS WITH HIV INFECTION AND AIDS**

HIV infection and AIDS are prevalent in developing countries. Heterosexual transmission and perinatal transmission are common; young children and young adults of both genders are primarily infected. Patients presenting to the ED may be coinfected with HIV and any other infectious agent, including all the parasites discussed in this chapter. HIV co-infection may worsen the symptoms and outcome, alter the presentation, increase the virulence, or assist the infective process.

AIDS causes abnormalities in almost every aspect of a host’s immune response to infection; cell-mediated immunity, which is important in combating parasitic infection, is most affected. The diagnosis and response to therapy of many parasitic infections are monitored serologically. HIV infection interferes with this response, rendering many of these tests unreliable. Therapies that are extremely effective in the normal host may be ineffective in a patient with HIV infection. Pharmacologic agents may have to be given for long periods or for the patient’s entire life.

**Specific Parasites**

Malaria is not an opportunistic infection in patients with AIDS; however, many patients, especially children, with recurrent malaria and anemia from hemolysis have required transfusions from blood supplies not screened for HIV and have become infected. In regions where malaria is endemic, it is a common practice to treat most febrile patients with antimalarials. Some antimalarials are sulfonamides. Patients with AIDS have more severe allergic reactions to drugs, especially sulfonamides. Fever alone is not predictive of malaria in patients with AIDS; therefore, diagnosis should precede therapy. Patients with HIV infection are at greater risk for severe clinical manifestations of babesiosis.

Visceral leishmaniasis is usually disseminated and fatal in patients with AIDS. Latent leishmanial infections may be reacti- vated, and a prolonged febrile illness in an HIV-positive patient with a lifetime history of travel in leishmaniasis-endemic areas of the world should prompt consideration of this co-infection. Cutaneous infection also may become disseminated in these patients. Several clinical trials have been examining the role of chemoprophylaxis for leishmaniasis in HIV-positive persons who live in endemic regions. Chagas’ disease in the indeterminate phase can be reactivated in patients infected with HIV. These patients frequently have CNS involvement, with meningoencephalitis and severe myocarditis. Single-drug therapy may be insufficient because benzimidazole penetration into the CSF is minimal.

**T. gondii** infection is well recognized throughout the world as a common opportunistic infection of patients with AIDS, with a particular trophism for the CNS.

The coccidial organisms *Isospora belli*, *C. parvum*, and *C. cayetanensis* have been associated with prolonged diarrhea in patients with AIDS. These organisms cause infections that are difficult to treat and are almost impossible to eradicate in these patients. The diarrhea is extremely debilitating and can be as profuse as that seen in cholera.

*E. histolytica* has a high prevalence among homosexual men who practice unprotected anal intercourse; however, invasive amebiasis is not an opportunistic infection associated with HIV infection.

Schistosomiasis enhances the pathogenesis of HIV infection and is more difficult to treat and eradicate in patients who are HIV-positive. *S. stercoralis* infection is more likely to be manifested as hyperinfection and disseminated disease in patients who are HIV-positive. In patients who are at risk for HIV infection and parasitic illness, it is essential to consider coinfection in the differential diagnosis.

**KEY CONCEPTS**

- Parasitic diseases may manifest with almost any symptom or constellation of signs and symptoms. Accordingly, a travel history should be obtained from all patients with clinically significant signs and symptoms of unclear cause. The combination of presenting signs and symptoms and a history of recent travel to specific geographic regions can lead to early diagnosis and the initiation of pharmacotherapy, decreasing morbidity and mortality and increasing the probability of eradication of the infection.
- Parasitic coinfections are particularly common in patients with HIV infection and AIDS. A travel history is essential because the clinical presentation may be atypical, morbidity and mortality are more severe, and treatment and eradication of the parasite are often prolonged.
- Acute malaria should be suspected in patients with irregular high fevers associated with headache, abdominal pain, or respiratory symptoms. Falciparum malaria, which has a unique morphology easily identifiable on the peripheral blood smear, is the only species of malaria that causes coma and death. Furthermore, it is the most highly resistant to chemotherapy, demanding close observation and clinical follow-up of patients. Patients who are clinically ill or who are suspected of having falciparum malaria should be hospitalized for evaluation and treatment.
- Cysticercosis should be considered in the differential diagnosis for new-onset seizures, especially in immigrants from Central and South America.
- Giardiasis should be suspected in patients with diarrhea who have recently been camping or drinking unfiltered mountain spring water. Patients may have tolerated several weeks of severe bloating, flatulence, eructation, and weight loss without fever before seeking medical attention.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
125.1. A 33-year-old man presents with irregular fevers, shaking chills, intermittent abdominal pain, and fatigue. The fever comes in cycles during approximately 2 or 3 days. He has no medical history and takes no medications. He works as a baggage handler in Miami, Florida. Physical examination reveals a low-grade fever and mildly tender hepatosplenomegaly. Laboratory evaluation is remarkable for hemoglobin 9.6 g/dL, leukocytosis, lactate dehydrogenase 1850 IU/dL, elevated bilirubin, and urine dipstick “blood positive” but no red blood cells or white blood cells. He has had no international travel. Peripheral smear reveals few possible parasites with fragmented red blood cells. What is this patient’s most likely infection?

A. Babesiosis
B. Early sepsis
C. Leishmaniasis
D. Lyme disease
E. Malaria

Answer: E. Airport malaria has been reported in people who have never been in endemic areas but who work in or live near an international airport. The infected mosquito is transported from the endemic region and released when the plane arrives. Babesiosis is a parasitic illness with a clinical picture like that of malaria. It is tickborne and is endemic in the northeastern United States.

125.2. A 21-year-old Hispanic male immigrant presents with new onset of seizures. Paramedics report a right upper extremity focused seizure with loss of consciousness and postictal period of approximately 20 minutes. He has had no previous seizures, symptoms, medications, trauma, or ingestions. Laboratory examination is normal except for HCO₃⁻ 17 mmol/L. Which of the following statements regarding the most likely cause of this patient’s seizures is TRUE?

A. A ring-enhancing lesion suggests HIV infection.
B. Albenzolide may be effective.
C. Contaminated beef ingestion should be suspected.
D. The stool examination will likely be negative.
E. There is no role for corticosteroids.

Answer: B. *Taenia solium* infection (cysticercosis) results from contaminated pork ingestion. The larval cestode penetrates the small intestine and may travel anywhere, with brain, muscle, and soft tissue being the likely areas of cyst occurrence with accompanying inflammatory reaction. The enlarging cyst (often a ring-enhancing lesion) causes the symptoms. Stool examination is diagnostic. Albendazole and corticosteroids are indicated for the central nervous system lesion. Postseizure acidosis is common and generally clears within 1 hour.

REFERENCES

**125.3.** Fever, headaches, and posterior cervical adenopathy in a recent African traveler should suggest which of the following?
A. Central nervous system amebiasis
B. Cysticercosis
C. Falciparum malaria
D. Schistosomiasis
E. Trypanosomiasis

**Answer:** E. Trypanosomiasis causes central nervous system inflammation and headache that may progress to psychiatric symptoms, lethargy, and coma. The posterior cervical adenopathy in this scenario is called Winterbottom's sign.

**125.4.** A macrocytic anemia would suggest infection from which parasite?
A. *Ancylostoma duodenale*
B. *Diphyllobothrium latum*
C. Falciparum malaria
D. *Necator americanus*
E. Whipworm

**Answer:** B. The fish tapeworm is associated with pernicious anemia. Hookworm and whipworm are associated with gastrointestinal iron loss and microcytic anemia. Malaria causes hemolytic anemia.

**125.5.** A 42-year-old man from Ethiopia presents with complaints of skin nodules and skin ulcerations. He has no known past illnesses, exposures, medication use, or systemic symptoms. Examination is remarkable for four 2- or 3-cm cutaneous ulcers on the arms and legs and scattered 1-cm nodules. Vital signs are normal, and physical examination is otherwise unrevealing. Which of the following statements regarding this infection is **TRUE**?
A. Respiratory tract symptoms would suggest an alternative diagnosis.
B. The lesions always require treatment.
C. The lesions are likely painful to touch.
D. The skin pattern may be confused with leprosy.
E. This infection does not affect mucocutaneous areas.

**Answer:** D. Leishmaniasis is transmitted by the sandfly bite. Skin papules and macules develop at bite sites. These may ulcerate into painless ulcers. A microcutaneous variant may be seen, and the inflammatory process may involve the larynx and trachea. Disseminated cutaneous leishmaniasis may resemble lepromatous leprosy.

**125.6.** Parasite-induced loss of vision would be suggested by which of the following?
A. Cardiomegaly
B. Edematous and pruritic skin
C. Fever
D. Hepatosplenomegaly
E. Iron deficiency anemia

**Answer:** B. Onchocerciasis is a major cause of blindness worldwide. Ninety-five percent of cases occur in Africa. The biting flies are found near rivers, and humans are the only host for the parasite. It occupies the skin, resulting in pruritus, edema, and later atrophy with redundant skin folds. The following are other causes of parasite-induced visual loss: *Toxoplasma* can cause retinal hemorrhages, *Toxocara* can cause inflammatory retinal granulomas, and *Acanthamoeba* may cause a keratitis in contact lens wearers.

**125.7.** Which of the following is the correct association between the type of parasitic infection and pulmonary symptoms?
A. Hookworm—positive PPD response
B. Leishmaniasis—pulmonary nodules
C. Löffler's syndrome—ascariasis
D. Pneumocystis—90% of opportunistic infections in Africa
E. Whipworm—anaphylaxis

**Answer:** C. Ascariasis and hookworm may cause Löffler's syndrome of chest pain, fever, rales, wheezing, and eosinophilia. The following are the other correct associations: *Pneumocystis*—less than 10% of pulmonary opportunistic infections in Africa *Paragonimus westermani*—positive tuberculin skin test response and chest radiograph resembling tuberculosis *Echinococcus*—anaphylaxis from leakage of cystic contents *Schistosomiasis*—diffuse pulmonary nodules (Katayama fever)

**125.8.** Which of the following statements regarding AIDS and parasitic infections is **TRUE**?
A. AIDS patients have more severe reactions to antiparasitic agents.
B. Diarrheal illness is reliably eradicable.
C. Invasive amebiasis is an opportunistic infection.
D. Malaria is an opportunistic infection.
E. Parasitic illnesses do not enhance the pathogenesis of HIV infection.

**Answer:** A. *Isospora* and coccidial organisms may cause an almost cholera-like diarrheal illness. Eradication is very difficult. Malaria and invasive amebiasis are not considered opportunistic infections. AIDS patients have much more severe allergic manifestations to the antiparasitics. Schistosomiasis enhances HIV pathogenesis.

**125.9.** A 34-year-old man presents with 2 weeks of fever with temperature of up to 102° F, anorexia, and 5-pound weight loss. He had recently been traveling in Central America in Belize, Nicaragua, and Guatemala. He had done some camping but mostly stayed in hostels. He never had nausea, vomiting, or diarrhea. His physical examination is noteworthy only for right upper quadrant tenderness and a palpable liver edge. He is not icteric or jaundiced and denies chalky stools or dark urine. He has a white blood cell count with a left shift. His transaminases are elevated, but otherwise his laboratory results are relatively normal. Stool examination for ova and parasites is negative. What is the most likely diagnosis?
A. *Entamoeba histolytica* infection
B. *Fasciola hepatica* infection
C. Hepatitis A
D. Hepatitis B
E. *Schistosoma mansoni* infection

**Answer:** A. *Entamoeba histolytica* infection with a hepatic abscess. *E. histolytica* can cause hepatic abscesses. Affected patients typically do not have amebic dysentery and do not shed *Entamoeba* in their stool, but results of serologic studies almost always are positive. Patients have fever, weight loss, anorexia, and right-sided abdominal pain but no jaundice. Treatment is with metronidazole or tinidazole and a luminal amebicide, such as iodoquinol.
125.10. A 26-year-old female medical student presents with a 3-month history of diarrhea and a 20-pound weight loss. She has not had fevers, chills, cough, headache, or rash. Four months ago, she had done a rotation in Nepal working at a rural health clinic associated with an American medical school. Toward the end of her rotation, she began to develop diffuse abdominal bloating and discomfort. This was accompanied by flatulence and intermittent watery diarrhea. She felt like she had swallowed a basketball and all of her pants were “too tight.” “I thought I was pregnant, but my tests were all negative.” She had lost her appetite and was very worried by the weight loss. The results of her laboratory tests, including complete blood count, Chem-20, and stool for ova and parasites, were negative. What is the most likely diagnosis?

A. Cryptosporidium parvum or Cyclospora cayetanensis infection
B. Entamoeba histolytica infection
C. Giardia lamblia infection
D. Salmonella typhi infection
E. Shigella dysenteriae infection

Answer: C. Giardia lamblia can cause persistent diarrhea, abdominal bloating, cramps, flatulence, and significant weight loss. The organism is ingested and reproduces exponentially in the small bowel. In severe infection, the entire jejunum becomes covered with organisms, and the patient has malabsorption with steatorrhea. The organisms are rarely seen in fresh stool preparations because they quickly break down and become indiscernible. Accordingly, an antigen test often is used to confirm the diagnosis. Giardia has many animal reservoirs, including the beaver. Campers who drink unfiltered, pure mountain spring water in the United States commonly contract Giardia infection. Metronidazole, tinidazole, or nitazoxanide treats the disease.

125.11. A 64-year-old man recently emigrated from Laos is referred to the emergency department for fever, hemoptysis, anorexia, positive PPD response, and chest radiograph with several cavitary lesions. He had been started on a three-drug regimen for presumptive tuberculosis but seems to be getting worse. Several sputum samples had not grown out mycobacteria. He immigrated to the United States from Laos 6 months ago. He had lived in a rural district and worked farming rice before emigration. Through a translator, he reported having several bouts of pneumonia in the last year treated with antibiotics in Laos, but he never really got any better. He has had a persistent cough, which has gotten worse with recent hemoptysis. He has lost more than 20 pounds and appears cachectic and ill. Physical examination of the lungs reveals scattered rhonchi, rales, and wheezes. His complete blood count shows 12% eosinophils. What is the most likely diagnosis?

A. Löffler’s syndrome from Ascaris lumbricoides infection
B. Multiply drug resistant mycobacteria
C. Paragonimus westermani infection
D. Pseudomonas pseudomallei infection
E. Tropical eosinophilic pneumonitis from Wuchereria bancrofti infection

Answer: C. Paragonimus westermani is trophic for the lungs in their human hosts. If the human host consumes raw or undercooked shellfish, the metacercariae excyst within the host’s duodenum, penetrating the duodenal wall into the abdominal cavity. The larvae migrate from the peritoneal cavity through the diaphragm into the pleural cavity, finally migrating to the lungs, where they cause hemorrhage, necrosis, and a granulomatous response. Early in the process, patients may have infiltrates and eosinophilia; later disease is marked by bronchiectasis, chronic bronchitis, fever, hemoptysis, and cachexia. Pulmonary nodules and cysts may cavitate. Many of these patients may have a positive result on purified protein derivative (PPD) testing, and their symptoms and chest radiographic findings may mimic tuberculosis. Sputum often is blood streaked and flecked with dark brown particles containing ova. Finding of ova in sputum is diagnostic. Radiography, stool examination, and immune testing of sputum and blood are all helpful in making the diagnosis. Praziquantel is the therapeutic agent of choice.
Tickborne Illnesses
Edward B. Bolgiano | Joseph Sexton

OVERVIEW
Ticks are hemotaphagous parasites of humans and animals, distributed worldwide. They transmit rickettsial, bacterial, spirochetal, viral, and protozoal diseases and cause disease by means of their own toxins (Table 126.1). As vectors of human disease, ticks rank second in importance only to mosquitoes. Although it is generally understood that people who travel during the summer months may return from endemic areas with tickborne disease, increasing reports of infection acquired within urban areas emphasize the need to consider tickborne illness, even in the absence of a history of travel to high-risk areas. In addition, tularemia and Q fever are now considered by the Centers for Disease Control and Prevention (CDC) to be significant threats during biologic warfare. For this reason, research involving ticks and tickborne diseases has become increasingly important.

Reports on ticks, their feeding habits, and their possible relation to disease can be found from early human history. Pliny (ce 77), in Historia Naturalis, referred to “an animal living on blood with its head always fixed and swelling, being one of the animals which has no exit [anus] for its food, it bursts with over-repletion and dies from actual nourishment.” Tickborne illness was first recognized in the North American continent by Native Americans. According to legend, Shoshone men avoided the evil spirits that caused illness by sending only women into certain areas of the Rocky Mountain region known to be especially hazardous. The causative association of the tick vector with Rocky Mountain spotted fever (RMSF) was noted by missionaries and early settlers, who named the affliction tick fever, and physicians in Idaho and Montana recorded the classic clinical descriptions of the disease in 1899.

Identification of Ticks
Ticks are arthropods but not insects. They have eight legs instead of six and generally two fusing body parts—a capitulum (head) and opisthosoma (abdomen)—instead of three. Identification of an arthropod as a tick and subsequent categorization into family and some genera are not difficult (Figs. 126.1 and 126.2). Speciation requires a trained acarologist. However, tick identification has limited importance in clinical decision making. Color, which varies seasonally, and size, which varies by amount of blood ingested at the time of presentation, are unreliable criteria for identification purposes.

Physiology of Tick Feeding
An understanding of the physiology of feeding in arthropods is more essential than species identification when assessing the risks of transmission of diseases. Blood-sucking arthropods are divided into two groups according to their method of acquiring blood. The solenophagic feeders insert their mouthparts directly into capillaries to obtain blood. Telmophagic feeders insert their mouthparts indiscriminately, lyse tissue along with capillaries, and feed on the resultant pool of blood, extracellular fluid, and tissue. Ticks and deer flies, for example, are telmophagic feeders, whereas mosquitoes are mostly solenophagic.

Argasid ticks (soft-bodied ticks) are short, rapid feeders with preformed distensible endocuticles. They therefore need to feed for only minutes to hours to acquire a full meal. As a result, they tend to be found in nests and burrows where their hosts visit frequently. The genus Ornithodoros is the vector for relapsing fever. Ixodid ticks (hard-bodied ticks) include the genera Ixodes, Dermacentor, Amblyomma, and Rhipicephalus, which are those responsible for the remainder of human tickborne diseases in the United States discussed in this chapter. These ticks need to form a new exocuticle (phase I of feeding) and thus feed slowly during the first 12 to 24 hours. Once it is fully formed, the new endocuticle allows rapid feeding (phase II) and significant engorgement.

In the capitulum of ticks, the sucking structure, consisting of the chelicerae, is surrounded by a sheath from which it protrudes during feeding. When a suitable location is found, adjacent cheliceral digits incise the skin, and the chelicerae and barbed hypostome are inserted. Two mechanisms prevent the tick from being removed from the skin—the barbed hypostome and a cement-like salivary secretion from the base of the hypostome, composed of lipoproteins and glycoproteins. This allows ixodid ticks to remain attached for as long as 2 weeks. Because argasids are much faster feeders, they secrete no cement substance.

During a bite, trauma and salivary gland products can cause local inflammation, hyperemia, edema, hemorrhage, and skin thickening. The saliva injected during feeding contains many different substances. Hard and soft ticks produce a histolytic secretion that liquefies tissue, which is then sucked into the gut. Eventually, the secretion breaks down the walls of the dermal blood vessels and the released blood is ingested. To prevent hemostasis, the saliva contains a thrombokinase inhibitor, aprotase, which prevents platelet aggregation by depleting adenosine diphosphate, prostaglandin E2, and prostacyclin (prostaglandin I2) to prevent vasoconstriction, and cytolysins. Ixodes scapularis also secretes a carboxypeptidase that destroys other inflammatory mediators, such as anaphylatoxins and bradykinin, as well as anti-complement C3 factor. These other mediators normally would cause further inflammation, which would enhance hemostasis. All infectious agents and excretory liquids from some argasids are transmitted through this saliva. Transmission of a disease from Ixodes ticks is unlikely if the tick is not yet engorged with blood at the time of removal. Likewise, a tick removed within a few hours after attachment is unlikely to transmit disease. The neurotoxins responsible for tick paralysis are also found in tick saliva.

The local physiologic changes associated with tick feeding produce the characteristic 1- to 4-mm erythematous mark typically seen on the skin after a tick bite. This is a common finding from most blood-sucking arthropods. The mark should not be confused with certain rashes associated with disease progression—for example, erythema migrans. Informing patients of this difference may be reassuring.
LYME DISEASE

Lyme disease, the most common vector-borne disease in the United States, is a tickborne illness caused by the spirochete *Borrelia burgdorferi*. The story of Lyme disease began in 1975, when health officials at the Connecticut State Department of Health and physicians at Yale University were alerted by two skeptical mothers of an unusually large number of cases of apparent juvenile rheumatoid arthritis occurring in their small coastal community of Old Lyme, Connecticut. Investigation led to the description of a new entity called Lyme arthritis. The causative agent of Lyme disease was isolated in 1982. Lyme disease occurs worldwide and has been reported on every continent except Antarctica. It now accounts for more than 95% of all reported cases of US vector-borne illness. The actual overall incidence of Lyme disease is unknown because many cases go unreported. Lyme disease occurs in people of all ages but is more common in children younger than 15 years and in adults 30 to 60 years of age. Persons at greatest risk live or vacation in endemic areas. In the United States, three distinct endemic foci are recognized—the northeastern coastal, Mid-Atlantic, and north central states. During 2000, a total of 17,730 cases of Lyme disease were reported from 44 states and the District of Columbia. Twelve states (Connecticut, Maine, Maryland, Massachusetts, Minnesota, New Hampshire, New Jersey, New York, Pennsylvania, Vermont, Washington, and Wisconsin) accounted for 92% of US cases reported (Fig. 126.3).

The principal tick vectors are *I. scapularis* in the Northeast and Midwest and *Ixodes pacificus* in the West. The *I. scapularis* population density depends on that of its preferred hosts, the white-footed field mouse, *Peromyscus leucopus*, for the larval and nymphal forms, and the white-tailed deer, *Odocoileus virginianus*, for the adult form. The white-footed mouse readily becomes infected after being bitten by infected ticks and remains highly infectious for periods that approach its life span in nature, thereby providing an important reservoir for *B. burgdorferi*. Adult *I. scapularis* ticks feed primarily on deer, which are key hosts in the tick life cycle and in whose fur the adult tick may survive the winter. The repopulation of several areas in the United States by white-tailed deer preceded the recent emergence of Lyme disease in those regions. Although all stages of the tick may feed on humans, the nymph is primarily responsible for the transmission of Lyme disease. It is not surprising that more than two-thirds of patients with Lyme disease do not recall a tick bite, in view of the small size (1–2 mm) of nymphs (Fig. 126.4). The nymph feeds in the spring and summer, which correlates with a peak incidence of early Lyme disease occurring between May and August. In addition, recreational and occupational exposure is greatest during this time. Later manifestations of Lyme disease may appear throughout the year.

The spirochete *Borrelia burgdorferi* persists and multiplies in the midgut of its tick vector, *I. scapularis*. Transmission of the spirochete to humans occurs during feeding, generally about 2 days after attachment. The mechanism of transmission probably is inoculation with infectious saliva or, alternatively, with tick gut fluids periodically regurgitated during the feeding process. After an incubation period that lasts several days to several weeks, spirochetemia develops, and *Borrelia* organisms may migrate outward in the blood or lymph to virtually any site in the body. The spirochete appears to be tropic for synovial tissue, skin, and cells of the nervous system, but the mechanism of this tropism...
is not yet understood. Infection by the spirochete itself accounts for early clinical manifestations. It remains unclear whether late disease manifestations require the continued presence of viable spirochetes or whether an ongoing host immune response to initial infection is sufficient to cause some late disease effects. Although the exact roles of infecting spirochetes, spirochetal antigens, and host immune responses are unknown, it is likely that persistent live spirochetes are responsible for most later manifestations of the disease. The variable severity of Lyme disease may in part result from genetic variations in the human immune system. For example, patients with chronic Lyme arthritis have an increased frequency of human leukocyte antigen (HLA) specificity, in particular for HLA-DR4 and, less often, for HLA-DR2.

Clinical Features

Lyme disease, a multisystem disorder, can be classified into three stages—early localized, early disseminated, and late disease. Virtually any clinical feature may occur alone or recur at intervals, and some patients who had no early symptoms may have late symptoms. The disorder usually begins with a rash and associated constitutional signs and symptoms, suggesting a viral syndrome (early Lyme disease). Neurologic, joint, or cardiac manifestations may emerge weeks to months later (early disseminated Lyme disease), and chronic arthritic and neurologic abnormalities may appear weeks to years later (late Lyme disease). The time course for the clinical features of untreated Lyme disease is illustrated in Fig. 126.5.

Early Lyme Disease

Ticks may attach to human hosts at the initial point of contact, generally around ankle level, or move about until they encounter an obstruction. The groin, popliteal fossae, gluteal folds, axillary folds, and earlobes are common sites of attachment. After transmission of *B. burgdorferi* through a tick bite, the initial site of infection is the skin at the site of the bite. After an incubation period of approximately 1 week (range, 1–36 days), the spirochetes cause a gradually spreading localized infection in the skin and a resultant skin lesion, erythema migrans. Erythema migrans

**Fig. 126.5.** Natural history of serologic response, with clinical features, in untreated Lyme disease. IgG, immunoglobulin G; IgM, immunoglobulin M. (Adapted from Rahn DW: Natural history of Lyme disease. In Rahn DW, Evans J, editors: Lyme disease. Philadelphia, 1998, American College of Physicians, pp 35–48.)

(E.M.) is the most characteristic clinical manifestation of Lyme disease and is recognized in 90% or more of patients. EM may go unnoticed if the entire skin surface is not examined. The characteristic rash begins at the site of the tick bite with an erythematous papule or macule. The lesion expands gradually (1–2 cm/day, a rate of expansion slower than that of cellulitis). The patch of erythema may be confluent or may have bands of normal-appearing skin. Central clearing may occur but is not an invariable feature. The lesion borders usually are flat but may be raised. The lesions generally are sharply demarcated and blanch with pressure. Most lesions are oval or round, but triangular and elongated patches may occur. In patients presenting 1 to 7 days after the appearance of lesions, the average lesion size is approximately 8 by 10 cm (range, 2 by 3 cm to 25 by 25 cm). In some cases, the center of some early lesions becomes red and indurated or vesicular and necrotic. The lesion is warm to the touch and may be described by the patient as nontender to minimally tender (Figs. 126.6 and 126.7).

Hematogenous spread of viable spirochetes (not additional tick bites) may result in one or more secondary lesions. These secondary lesions are smaller, migrate less, and typically spare the palms and soles. In all, 10% to 15% of patients have more than 20 such lesions; on rare occasions, they may number more than 100. Blistering and mucosal involvement do not occur. The primary and secondary skin lesions generally fade after approximately 28 days (range, 1 week to 14 months) without treatment.

**Fig. 126.6.** Lyme disease usually begins with a slowly expanding skin lesion, erythema migrans, which occurs at the site of the tick bite. The classic bull’s-eye or target lesion has partial central clearing, a bright red outer border, and a target center. (From Bhate C, Schwartz RA: Lyme disease. Part I. Advances and perspectives. J Am Acad Dermatol 64:619–636, 2011.)

**Acute Disseminated Infection**

Shortly after disease onset, hematogenous spread can cause a variety of systemic signs and symptoms and result in secondary sites of infection. Organ systems commonly affected are the nervous system, heart, and joints. Less commonly, the eyes, liver, skeletal muscle, subcutaneous tissue, and spleen are infected.

**Neurologic Manifestations.** A relatively symptom-free interval usually occurs between early and disseminated infection; however, neurologic signs and symptoms may be the presenting manifestations of Lyme disease or may overlap with early or late manifestations. Beginning at an average of 4 weeks (range, 0–10 weeks) after the onset of erythema migrans, neurologic involvement occurs in approximately 15% of untreated patients.

The most common neurologic manifestation of Lyme disease is a fluctuating meningoencephalitis, with superimposed symptoms of cranial neuropathy, peripheral neuropathy, or radiculopathy. A triad of meningitis, cranial neuropathies (usually Bell’s palsy), and radiculopathy has been described, but each entity may occur alone. Headache of variable intensity usually is present; other signs and symptoms of a mild meningoencephalitis may be noted, including lethargy or irritability, sleep disturbances, poor concentration, and memory loss. At this point, the disease often

---

and within several days of antibiotic therapy. Recurrent lesions may develop in patients who do not receive antibiotic therapy but apparently not in those who receive appropriate antibiotics.

Constitutional signs and symptoms commonly appear in early Lyme disease (Table 126.2). Malaise, fatigue, and lethargy are most common (seen in ≈80% of patients) and may be severe. Fever typically is low grade and intermittent. Lymphadenopathy usually is regional in the distribution of EM or may be generalized; splenomegaly may occur. Musculoskeletal complaints, such as arthralgias and myalgias, are common, and the discomfort typically is short-lived and migratory, sometimes lasting only hours in one location. Frank arthritis may occur at this stage but is rare.

Clinical manifestations of meningeal irritation are frequently seen. Headache, the most common symptom, usually is intermittent and localized. Nausea, vomiting, and photophobia occasionally accompany the headache. Kernig’s and Brudzinski’s signs typically are absent, and neck stiffness usually is noted only on extreme forward flexion. At this stage, the neurologic examination and cerebrospinal fluid (CSF) assessment usually yield normal findings.

Signs and symptoms of hepatitis, including anorexia, abdominal pain, right upper quadrant tenderness, nausea, and vomiting, may be present. Mild pharyngitis also may be present, but other upper respiratory symptoms, such as rhinorrhea, do not occur. Although the systemic symptoms of early Lyme disease often are described as flulike, a term that can be misleading because clinically significant cough usually does not occur. Conjunctivitis develops in approximately 10% of patients.

The incidence of Lyme disease without EM appears to be approximately 10%. Because of the variety of nonspecific signs and symptoms at this stage, in the absence of the characteristic rash or history of tick bite, early Lyme disease may be easily confused with a viral or collagen vascular disease. The intermittent and rapidly changing nature of the early signs and symptoms of Lyme disease may be a helpful distinguishing feature, especially in a patient from an endemic area. In untreated disease, early symptoms usually last for several weeks but may persist for months.
is misdiagnosed as viral meningitis. As in early disease, Kernig’s and Brudzinski’s signs are absent and computed tomography (CT) findings are normal. Unlike in early disease, however, findings on CSF examination often are abnormal, with a lymphocytic pleocytosis and moderately elevated protein level. CSF glucose concentration usually is normal. Intrathecal B. burgdorferi antibody (usually immunoglobulin G [IgG] or IgA) is present in 80% to 90% of patients. CSF polymerase chain reaction (PCR) assay results are positive in less than 50% of patients, probably reflecting the low number of organisms usually present in spinal fluid. Routine testing of CSF by PCR assay is not recommended.

Cranial neuropathies are common, occurring in approximately 50% of patients with Lyme meningitis; the seventh nerve is usually involved. Other cranial nerves are affected less often. Bell’s palsy is bilateral in approximately one-third of patients. Its duration usually is weeks to months, and the condition generally resolves spontaneously without treatment.

Peripheral nervous system manifestations also may occur in early disseminated Lyme disease. The spinal root and plexus and peripheral nerves may be involved in the form of thoracic sensory radiculitis, brachial plexitis, mononeuropathy, and motor radiculoneuritis in the extremities. Patients may complain of weakness, pain, or dysesthesia. Examination may reveal loss of reflexes. Involvement of the extremities usually is asymmetric, but cervical and thoracic dermatomes may be affected. Other rare neurologic abnormalities described in association with Lyme disease include chorea, transverse myelitis, ataxia, and pseudotumor cerebri. Cerebral vasculitis associated with Lyme disease also has been reported.

**Cardiac Manifestations.** Cardiac involvement in Lyme disease is uncommon. Estimates of the incidence of carditis in untreated patients with Lyme disease range from 4% to 10%. Cardiac involvement occurs during the early disseminated phase of the disease. The average time from initial illness to the development of carditis typically is 3 to 5 weeks (range, 4 days to 7 months). Direct myocardial invasion has been demonstrated with endomyocardial biopsy. Electrophysiologic testing has demonstrated widespread involvement of the conduction system.

The most common cardiac manifestation of Lyme disease is atrioventricular (AV) block, although conduction defects may involve any level of the conducting system. Myopericarditis, tachydysrhythmias, and ventricular impairment occur less often. In a review of 105 reported cases of Lyme carditis, 49% of cases were third-degree, 16% were second-degree, and 12% were first-degree AV block. The degree of AV block seen in a specific patient may fluctuate rapidly.

A commonly observed feature of AV block in patients with Lyme carditis is its gradual resolution, resembling that occurring after an acute inferior wall myocardial infarction and presumably related to the resolution of inflammation. Assessment of the level of the AV block is important to determine the prognosis of a patient with Lyme carditis. In most cases, the block appears to be at or above the level of the AV node; therefore, the prognosis is favorable. However, infranodal AV block does occur and may be characterized by slow escape rhythms of wide QRS pattern, asystole, or fluctuating left and right bundle branch block. Other electrocardiographic findings include nonspecific ST and T wave abnormalities and intraventricular conduction delay.

Patients with high-degree AV block usually are asymptomatic. Symptoms include lightheadedness, palpitations, syncope, chest pain, and dyspnea on exertion. The physical examination may reveal flow murmurs and murmurs of mild mitral regurgitation, pericardial friction rub, or evidence of congestive heart failure. Associated left ventricular dysfunction may be present and has been documented by two-dimensional echocardiography and radionuclide studies; in most reported cases, it has been mild and transient. Sudden cardiac death attributable to Lyme disease has also been reported.2,4

**Arthritis.** Although it is generally considered a sign of late Lyme disease, acute arthritis may begin during the acute disseminated stage. Monarticular or oligoarticular arthritis, primarily affecting large joints, especially the knee, may develop weeks to months after the onset of initial illness. In an early study of the natural history of Lyme arthritis, approximately 50% of untreated patients experienced one episode or multiple intermittent attacks of arthritis. Acute arthritis typically is monarticular, with involvement of only one knee. The shoulder, elbow, temporomandibular joint, ankle, wrist, hip, and small joints of the hands and feet are involved less commonly. Episodes of arthritis typically are brief (lasting weeks to months) and are separated by variable periods of remission.

Arthrocentesis generally is nondiagnostic, yielding an inflammatory synovial fluid with a mean white blood cell count of approximately 25,000 cells/µl (75% polymorphonuclear leukocytes). Higher white blood cell counts have been reported, simulating septic arthritis. The synovial glucose concentration usually is normal, and protein levels are variable, ranging from 3 to 8 g/dl. Cultures of the fluid rarely identify the causative spirochete. The complement level generally is greater than one-third that of serum. Synovial biopsy reveals hypertrophy, vascular proliferation, and a mononuclear cell infiltrate. Findings therefore are similar to those in rheumatoid arthritis, except that rheumatoid factor and antinuclear antibody assays yield a negative result in Lyme arthritis. Radiography may reveal nonspecific abnormalities such as juxtaarticular osteoporosis, cartilage loss, cortical or marginal bone erosions, and joint effusions.

**Ophthalmic Manifestations.** Ocular involvement also may be seen in early disseminated disease; manifestations include conjunctivitis, keratitis, choroiditis, retinal detachment, optic neuritis, and blindness. These findings also may be seen in late disease.

**Late Lyme Disease**

The chronic phase of Lyme disease is characterized by arthritic and, less commonly, neurologic symptoms. Transition from a pattern of episodic inflammation in early disease to a more indolent persistent inflammation is observed over time. The term chronic (or late) Lyme disease is used to describe continuous inflammation in an organ system for more than 1 year.

A pattern of exacerbation and remission of arthritis may extend for several years, with a gradual tendency toward less frequent and less severe occurrences. The spontaneous long-term remission rate approximates 10% to 20% annually in untreated patients. However, patients commonly have episodes of periarticular involvement, arthralgias, or fatigue interspersed between attacks of frank arthritis. During the second or third year of illness, attacks of joint swelling sometimes become longer in duration, lasting months rather than weeks. Chronic arthritis eventually develops in approximately 10% of patients.

Late neurologic complications include a wide variety of abnormalities of the central and peripheral nervous systems, as well as fatigue syndromes. Diagnosis may be difficult because of the large number of other neurologic conditions that Lyme disease may mimic and because late neurologic symptoms may be the first symptoms of the disease. The manifestations of chronic neuroborreliosis usually appear months to years after the onset of infection.

The most common late neurologic manifestation of Lyme disease is a chronic encephalopathy that is manifested as a mild to moderately severe impairment of memory and learning.
Hypersonomolence and mild psychiatric disturbances (depression, irritability, paranoia) also may develop.

Peripheral nervous system manifestations often are seen in late disease, with involvement of cranial nerves, spinal roots, spinal plexuses, and peripheral nerves. A predominantly sensory polyradiculoneuropathy that is manifested as radicular pain or distal paresthesia is common. Significant overlap occurs with early symptoms. Less commonly, a demyelinating condition resembling multiple sclerosis may appear in late disease. Symptoms are variable and, as in multiple sclerosis, may undergo exacerbations and remissions. CT and magnetic resonance imaging (MRI) may reveal multiple white matter lesions.

Chronic inflammation also may occur in the skin, causing a seldom-recognized late cutaneous manifestation of Lyme disease, acrodermatitis chronica atrophicans. This condition usually involves the skin of distal extremities at the site of a tick bite. It is characterized in its initial stages by an edematous infiltration, which progresses to an atrophic lesion resembling localized scleroderma in its more established form. B. burgdorferi has been demonstrated in the skin of patients with acrodermatitis chronica atrophicans as well as positive findings on serologic studies.

**Differential Diagnosis**

The diagnosis of Lyme disease should be considered on the basis of clinical and epidemiologic features. Identification of the disorder often is difficult, however, especially in the early stage. Although Lyme disease is manifested in many ways, each stage has characteristic clinical findings that are helpful in narrowing the scope of a differential diagnosis, which at first may seem overwhelmingly broad. Early Lyme disease (EM and associated constitutional symptoms) may be easily confused with a variety of other diseases, especially if the characteristic rash of EM is absent. A common clinical presentation is an influenza-like illness with headache, nausea, fever, chills, myalgias, arthralgias, stiff neck, and anorexia, occurring during the summer months. Even in endemic areas during the summer months, most patients with such symptoms do not have Lyme disease. When headache and stiff neck are the predominant symptoms, the principal diagnostic distinction to be made is between Lyme disease and the enteroviral diseases (and other causes of aseptic meningitis). The enteroviral diseases also have their peak incidence during the summer months; however, diarrhea, commonly associated with enteroviral infection, is not a feature of Lyme disease. Abdominal pain, anorexia, and nausea suggest hepatitis, sore throat, adenopathy, and fatigue suggest mononucleosis, and myalgias and arthralgias suggest connective tissue diseases. In many areas where Lyme disease is endemic, _Ixodes_ ticks can be infected simultaneously with _B. burgdorferi, Anaplasma phagocytophilum_, and _Babesia microti_. Co-infection with more than one of these agents can occur.

The rash of EM is characteristic of but not pathognomonic for Lyme disease. Some patients are not aware of having had such a rash and, in others, its appearance is atypical. An EM skin lesion is frequently misdiagnosed as a spider bite or community-acquired methicillin-resistant _Staphylococcus aureus_ (MRSA) cellulitis, resulting in treatment with ineffective antibiotics. Other cutaneous entities in the differential diagnosis for EM include fungal infection, plant dermatitis, and fixed drug eruptions. Secondary lesions may be confused with the target lesions of erythema multiforme, which generally are smaller and nonexpanding. Erythema multiforme also may involve the mucous membranes, palms, and soles; EM does not. The presence of a malar rash in association with Lyme disease suggests systemic lupus erythematosus. Erythema nodosum generally causes more painful induration than EM and has a predilection for the extensor surfaces of the legs. Erythema marginatum of acute rheumatic fever also is in the differential diagnosis for EM; the Lyme disease rash differs in comprising generally fewer, larger, less evanescent lesions that migrate more slowly. Atypical EM manifesting as a urticarial rash may suggest hepatitis B infection or serum sickness. Lyme disease should be considered in a patient with any atypical rash accompanied by a viral syndrome or meningitis-like illness, especially during the months of peak incidence.

Acute rheumatic fever, coronary artery disease, or viral myocarditis may be suggested by the cardiac manifestations of Lyme disease. The carditis of Lyme disease, like the carditis of rheumatic fever, may follow pharyngitis and migratory polyarthritis. Erythema marginatum usually occurs with the onset of arthritis, in contrast with EM, which usually precedes the carditis. Although some patients with Lyme disease may satisfy the clinical aspects of the Jones criteria for acute rheumatic fever, they lack evidence of a preceding streptococcal infection; in addition, valvular involvement is not a prominent feature of Lyme carditis.

The differential diagnosis of the neurologic manifestations caused by Lyme disease is extensive. Considerations include aseptic meningitis, herpes simplex encephalitis, Bell’s palsy of other causes, multiple sclerosis, Guillain-Barré syndrome, dementia, primary psychosis, cerebral vasculitis, and brain tumor. Neurologic symptoms often occur in the absence of any epidemiologic clues or preceding clinical symptoms suggestive of Lyme disease, making the diagnosis particularly challenging.

Lyme arthritis may mimic other immune-mediated disorders. The arthritis of Lyme disease generally is asymmetric, oligoarticular, and episodic. In contrast to patients with rheumatoid arthritis, those with Lyme arthritis rarely have symmetric polyarthritis, morning stiffness, a positive result on rheumatoid factor assay, or subcutaneous nodules. Lyme arthritis commonly is mistaken for seronegative rheumatoid arthritis; however, Lyme arthritis is most similar to the spondyloarthropathies, particularly reactive arthritis. Lyme disease and reactive arthritis both commonly cause huge knee effusions but, in Lyme disease, absence of the extraarticular features of reactive arthritis (conjunctivitis, urethritis or cervicitis, balanitis, keratitis, blepharoconjunctivitis) at the time of the arthritis helps distinguish it from reactive arthritis. In children, Lyme arthritis may mimic juvenile rheumatoid arthritis, but joint involvement in Lyme disease usually occurs in short intermittent attacks, and iridocyclitis typically is absent. Rheumatoid factor titers will be negative in juvenile rheumatoid arthritis and Lyme disease. The diseases resemble one another closely enough to have been confused at the time of the initial description of Lyme disease. Other diseases in the differential diagnosis for Lyme arthritis include acute gouty arthritis, septic arthritis, gonococcal arthritis, rheumatic fever, polymyalgia rheumatica, and temporomandibular joint syndrome.

**Diagnostic Testing**

Results of routine laboratory studies are nonspecific, and such studies generally are not helpful in the diagnosis of Lyme disease. Abnormalities may include an elevated erythrocyte sedimentation rate, mild anemia, total white blood cell count in the normal range with a decreased absolute lymphocyte count, microhematuria, proteinuria, and increased alanine transferase level. Cultures of blood, tissue, and body fluids (including CSF and synovial fluid) for _B. burgdorferi_ and direct visualization techniques are difficult to perform properly and have such a low yield that they are not clinically useful.

Serologic testing is the most practical and useful means of confirming a clinical diagnosis of Lyme disease, but is not without limitations. Results of serologic tests should be interpreted cautiously within the clinical context, and such tests should be regarded only as adjuncts in the diagnostic process. Current serologic tests measure host antibody response (for IgG and IgM) to _B. burgdorferi_. Problems with the performance of these tests and
interpretation of their findings often result in diagnostic confusion. False-negative and, especially, false-positive results are common. The antibody response to *B. burgdorferi* develops slowly. The peak of IgM titers appears between 3 and 6 weeks after the onset of illness. Earlier in the course of the illness, IgM titers may be negative. IgM antibody usually returns to nondiagnostic levels 4 to 6 weeks after the peak, but elevations may persist. IgG antibody may be detectable 2 months after exposure and peaks at approximately 12 months. Early antibiotic therapy may blunt or even abolish the antibody response.

A two-tier strategy is recommended for serologic testing—a sensitive enzyme-linked immunosorbent assay (ELISA) followed by a Western blot (immunoblot). Positive or equivocal ELISA results should be followed by a Western blot. If the ELISA is negative, no further testing is necessary.

IgM and IgG immunoblots should be obtained if early disease is suspected. If late disease is suspected, IgG Western blot alone should be obtained. Criteria for positive Western immunoblotting (requiring the presence of bands at particular locations) have been adopted by the CDC.

About one-third of patients with early localized Lyme disease (erythema migrans) are seropositive at the time of presentation by the two-tier method. Patients with skin lesions typical of EM do not require confirmatory serologic testing, and the rash itself is sufficient for the diagnosis to be made. If the cause of the rash is uncertain, acute and convalescent phase serologic testing may be considered, with the convalescent sample drawn 2 to 4 weeks after the acute sample. In contrast to early localized disease, most patients with early disseminated Lyme disease or late Lyme disease are seropositive.

IgG (and occasionally IgM) antibody may persist for several years after adequate treatment and symptom resolution. Persistent seropositivity is not diagnostic of ongoing infection. Even an IgM response cannot be interpreted as a demonstration of recent infection or reinfection unless the appropriate clinical characteristics are present. IgG antibody that developed after natural infection does not always confer immunity against future infection by *B. burgdorferi*. Patients who are treated for EM may become reinfected; patients with Lyme arthritis, however, usually have high antibody titers to many spirochetal proteins and seem not to become reinfected. Thus, the expanded immune response of late disease appears to be protective against reinfection, at least in most patients, whereas the immature immune response of early disease does not.

False-positive ELISA results are common. Serologic cross-reactivity can occur between *B. burgdorferi* and other spirochetes, most notably *Tetanoiella pallidum*. False-positive results for Lyme disease also can occur with relapsing fever, gingivitis, leptospirosis, enteroviral and other viral illnesses, rickettsial diseases, autoimmune diseases, malaria, and subacute bacterial endocarditis. In addition, it is estimated that up to 5% of the normal population will test positive for Lyme disease by ELISA. Bayes' theorem states that if the pretest likelihood of the disease is low, the positive predictive value is low: a positive test result is more likely to be a false-positive result. For this reason, screening serologic tests are not indicated in the absence of objective clinical evidence of Lyme disease.

Patients suspected of having acute Lyme neuroborreliosis should be evaluated with serologic tests and routine CSF examination. Paired serum and CSF samples should be obtained to evaluate for intrathecal production of antibody, although most patients with neuroborreliosis have positive results on serum serologic testing, thereby making additional laboratory confirmation with CSF serology unnecessary. The PCR assay has low sensitivity when performed on CSF and is not routinely recommended. However, the PCR assay is superior to culture for the detection of *B. burgdorferi* in synovial fluid and has a sensitivity of 73% and specificity of 99% in untreated Lyme arthropathy.

**Management**

Prompt treatment of early disease can shorten the duration of symptoms and prevent progression to later stages of disease. Most of the various manifestations of Lyme disease can be treated successfully with oral antibiotic therapy, with the exception of neurologic abnormalities, which usually require intravenous (IV) therapy. Treatment of Lyme disease is summarized in Table 126.3.

**Early Disease**

Prompt antibiotic therapy is essential in early Lyme disease because it generally shortens the duration of the rash and associated symptoms and, more importantly, prevents later illness in most patients. Some patients with severe early disease, however, progress to later stages, despite appropriate antibiotic regimens.

The drug of choice for men, nonpregnant and nonlactating women, and children older than 8 years is doxycycline, 100 mg bid for 3 weeks. An advantage of doxycycline is that it also is effective for the treatment of human granulocytic anaplasmosis, which is transmitted by the same tick that transmits Lyme disease. Pregnant or lactating women and children younger than 8 years should receive amoxicillin, 500 mg orally (20 to 40 mg/kg/day in three doses for children). Cefuroxime axetil has been shown to be as effective as doxycycline and may be used in children of any age, but cephalaxin is ineffective in Lyme disease.

Macrolide antibiotics are not recommended as first-line agents for therapy for early Lyme disease. They should be reserved for patients who cannot tolerate doxycycline, amoxicillin, and cefuroxime axetil. Macrolide regimens for adults include azithromycin, 500 mg orally daily for 7 to 10 days, erythromycin, 500 mg orally qid for 14 to 21 days, and clarithromycin, 500 mg orally bid for 14 to 21 days.

A Jarisch-Herxheimer type of reaction may occur in the first 24 hours of antibiotic treatment, consisting of fever, chills, myalgias, headache, tachycardia, increased respiratory rate, and mild leukocytosis. Defervescence usually takes place within 12 to 24 hours. The pathogenesis of this reaction is controversial, but it probably is caused by the killing of spirochetes, with the release of pyrogens. The Jarisch-Herxheimer reaction occurs more commonly with penicillin and doxycycline than with erythromycin, probably because of their superior spirochetal activity.

**Early Disseminated Infection**

**Neurologic Disease.** For patients with relatively mild symptoms (eg, solitary facial nerve palsy with normal findings on CSF examination), doxycycline or amoxicillin can be used in the same dosage as for early disease, but the duration of therapy should be extended to 28 days. The use of prednisone for facial nerve palsy from Lyme disease has been suggested but is not currently recommended.

Parenteral antibiotic therapy is required for patients with other objective neurologic abnormalities (eg, meningitis or encephalitis, peripheral neuropathies, cranial neuritis other than facial nerve palsy) or evidence of the spirochete in the CSF. Ceftriaxone, 2 g/day IV for 14 days (75 to 100 mg/kg/day for pediatric patients), or penicillin G, 18 to 24 million units daily IV for 10 to 14 days, may be used. Ceftriaxone may be more effective than penicillin, and many experts recommend longer courses (eg, up to 4 weeks). In cases of penicillin or cephalosporin allergy, oral doxycycline may be used for 28 days.

**Cardiac Disease.** Patients with mild cardiac conduction system involvement (first-degree AV block with a PR interval < 0.30 second) and no other significant symptoms usually can be treated safely on an outpatient basis with oral doxycycline or
amoxicillin for 21 to 30 days. Patients with higher degrees of AV block, including first-degree block with a PR interval of more than 0.30 second or evidence of global ventricular impairment, should be hospitalized for cardiac monitoring and treatment with parenteral antibiotics. Penicillin G, 18 to 24 million units IV in 4 divided doses, or ceftriaxone, 2 g daily for 21 days (50 to 80 mg/kg/day for children), may be used.

The benefit of the adjuvant use of aspirin or prednisone in the treatment of Lyme carditis is uncertain. Temporary cardiac pacing may be necessary in patients who have severe heart block with hemodynamic instability. The block generally resolves completely with antibiotic treatment, so the recognition of Lyme carditis in young patients with unexplained heart block is critical for avoidance of unnecessary permanent pacemaker implantation.

Late Infection

Arthritis. In established Lyme arthritis, the response to antibiotic therapy may be delayed for several weeks or months. An oral regimen for 30 days, such as doxycycline, 100 mg orally bid, or amoxicillin, 500 mg tid, usually are effective and, for reasons of cost and convenience, may be selected as first-line therapy given on an outpatient basis before parenteral antibiotic therapy is considered. Persistent or recurrent joint swelling after recommended courses of antibiotic therapy can be treated with another 4-week course of oral antibiotics or with a 2- to 4-week course of IV ceftriaxone. A small percentage of patients with Lyme arthritis, particularly those with HLA-DR4 specificity or antibody reactivity with OspA, may have persistent joint inflammation, despite treatment with oral or IV antibiotics. Such patients often do not respond to any antibiotic therapy and may require arthroscopic synovectomy.

"Pediatric dosage should not exceed adult dosage.
Tetracycline, 250 to 500 mg PO qid, may be substituted for doxycycline. Neither doxycycline nor any other tetracycline should be used for children younger than 8 years or for pregnant or lactating women.
Regimens for radiculoneuropathy, peripheral neuropathy, and encephalitis are the same as those for meningitis.
Oral regimens are reserved for mild cardiac involvement (see text).
Lyme Disease and Pregnancy

Similar to the spirochetal agents of syphilis and relapsing fever, *B. burgdorferi* can be passed transplacentally. In rare cases, Lyme disease acquired during pregnancy may lead to infection of the fetus and possibly to stillbirth, but adverse effects on the fetus have not been documented conclusively. Counseling about the termination of a pregnancy because of maternal Lyme disease is unwarranted.

Lyme disease contracted during pregnancy can be treated and cured. Treatment of pregnant patients can be identical to that of nonpregnant patients with the same disease manifestations, except that doxycycline should be avoided. Most women give birth to normal infants despite documented *Lyme* borreliosis during their pregnancies.

Vaccination

No vaccine against Lyme disease is currently available in the United States. The LYMErix vaccine (SmithKline Pharmaceuticals, Philadelphia), initially licensed in 1999, was withdrawn from the market in 2002. The vaccine, directed against the outer surface protein A of *B. burgdorferi* (OspA), was apparently safe and efficacious but required multiple and repeated doses for optimal protection. Ongoing questions about its safety and cost-effectiveness dampened demand for the vaccine.

A history of vaccination with the previously licensed vaccine should not change the approach to management. Because protective immunity produced by the vaccine is short-lived, it is unlikely that previous vaccination will provide any residual protective effect. Vaccination may cause a persistently positive ELISA result but a negative Western blot result.

Prophylaxis and Asymptomatic Tick Bites

Although previous expert consensus has recommended that persons bitten by deer ticks (*I. scapularis*) should not routinely receive antimicrobial chemoprophylaxis, this recommendation should be modified in accordance with the findings of a well-designed trial in which a single 200-mg dose of doxycycline given within 72 hours after tick bite effectively prevented Lyme disease. A single 200-mg dose of doxycycline should be considered for adult patients and children 8 years of age and older (4 mg/kg, up to a maximum dose of 200 mg) when all the following criteria are met: (1) the tick is an adult or nymphal *I. scapularis*; (2) the tick has been attached for 36 hours or more, as indicated by certainty of the time of exposure or degree of engorgement; (3) prophylaxis can be started within 72 hours after tick removal; (4) the local rate of infection of these ticks with *B. burgdorferi* is 20% or greater; and (5) doxycycline is not contraindicated. Infection rates of 20% or greater of ticks with *B. burgdorferi* are reported from highly endemic areas such as New England, parts of the Mid-Atlantic region, and parts of Minnesota and Wisconsin. Most other areas of the United States do not have infection rates high enough to warrant prophylaxis.

The efficacy of single-dose doxycycline in patients who present more than 72 hours after removal of a tick is unknown. In children, the dosing and efficacy of prophylactic treatment have not been evaluated. The effectiveness of doxycycline for the prevention of other infections transmitted by *I. scapularis* ticks (eg, babesiosis, human granulocytic anaplasmosis) is unknown and should not be assumed. Other antimicrobial agents effective for the treatment of Lyme disease (eg, amoxicillin) and even other regimens of doxycycline (eg, 100 mg bid) have unknown efficacy for Lyme disease prophylaxis. Anyone who has been bitten by a tick should be instructed to seek medical evaluation if symptoms of tick borne illness develop.

RELAPSING FEVER

Relapsing fever is caused by bacteria of the *Borrelia* species, order Spirochaetales. Human *Borrelia* infections occur worldwide, and all are associated with arthropod vectors. The epidemic (louse-borne) form of relapsing fever is caused solely by *Borrelia recurrentis* and is found mostly in Africa, where mortality rates can reach 70% with outbreaks. The endemic form, tick borne relapsing fever (TBRF), is caused by a group of closely related *Borrelia* species, their names derived from the species names of *Ornithodoros* tick vectors that carry them. The more common species in North America are *Borrelia hermsii*, *Borrelia turicatae*, and *Borrelia parkeri*. *B. burgdorferi* has been recognized as the causative agent of the third and most recently described borrelial disease, Lyme disease.

TRIS is maintained in an animal reservoir consisting primarily of wild rodents, including squirrels, mice, rats, chipmunks, and rabbits. It is found predominantly at altitudes of 2000 to 7000 feet in coniferous forest habitats. The tick vectors are argasids (soft ticks) belonging to several species of the genus *Ornithodoros*, which routinely reside in the nests and burrows of their mammalian hosts. Ticks acquire the infection by feeding on a spirochetic rodent. The borreliae remain viable in the ticks for several years and can be passed transovarially to the next generation; thus, the tick is a major reservoir and vector. These soft ticks feed for brief periods (15–20 minutes), usually at night, and their painless bite generally is unnoticed by the sleeping victim. Transmission occurs by injection of infected saliva through the bite site or intact skin. Less common modes of transmission (eg, by way of venipuncture equipment in injection drug users) have been reported.

In the United States, TBRF occurs primarily in the western Mountain and Pacific states, including Montana, Wyoming, Nevada, Colorado, California, and Washington. Between 1990 and 2011, the CDC received 504 reports of TBRF. The groups most commonly affected were males and people between the ages of 10 to 14 and 40 to 44 years. Of all reported cases, 70% were collectively from California, Washington, and Colorado. Most cases involved visitors to those states. Although TBRF is not nationally reportable, it was reported in 12 states in 2011. Persons who come into contact with infected ticks from wild rodents are at greatest risk. Outbreaks have been reported among groups of persons sleeping overnight in hunting cabins inhabited by wild rodents. In Texas, most cases were reported in the winter months among people who had been exploring caves.

Clinical Features

In TBRF, the initial febrile episode lasts 3 days. This is followed by an asymptomatic period of variable duration, usually approximately 7 days, during which patients generally feel better and may return to their usual daily activity levels under the assumption that they have recovered from another viral illness. Relapse then occurs, with symptoms that mimic those of the original illness. With TBRF, this cycle repeats itself three to five times. Each successive relapse usually is less severe. Relapse is caused by the spirochete’s unique ability to undergo antigenic variation within the body of the infected host. Each successive antigenic variation is cleared from the bloodstream by specific host antibodies, and a characteristic relapsing febrile course results.

Clinical illness is manifested in two classic stages as each fever episode resolves. The first stage is called the chill phase (high fevers with reported temperatures of up to 106.7°F (41.5°C), mental status changes, tachycardia, and tachypnea), lasting approximately 30 minutes, followed by a flush phase (rapid temperature decrease, sweats, and hypotension), which can be confused with a Jarisch-Herxheimer reaction.
After a postbite incubation period of 4 to 18 days, during which time the host concentration of spirochetes increases, fever of abrupt onset occurs, often accompanied by shaking chills, headache, arthralgias, myalgias, nausea, and vomiting. On occasion, a pruritic eschar may be noted at the site of the tick bite, but this usually is absent by the onset of clinical symptoms. Consequently, the nonspecific nature of the clinical presentation often leads to misdiagnosis of the disease as a viral illness. The patient’s temperature is high, and generalized muscle weakness and lethargy are common. Hepatomegaly, splenomegaly, and jaundice are sometimes seen. Neurologic involvement is less common but can be manifested as delirium, nuchal rigidity, peripheral neuropathy, or pupillary abnormalities. Uveitis, iritis and other cranial neuropathies can present acutely or, rarely, as long-term sequelae. A macular or petechial rash, more apparent on the trunk than on the extremities, may be present. There is evidence that febrile illness caused by relapsing fever might cause *Plasmodium vivax* malaria relapse.\[6\]

Severe cases of TBRF resulting in acute respiratory distress syndrome (ARDS) in California and Nevada near the Lake Tahoe area and in the state of Washington prompted a comprehensive epidemiologic investigation of cases in those areas during a 10-year period. This study showed that ARDS may be more common than was previously suspected. Reported occurrence rates for Jarisch-Herxheimer reaction varied between 6% and 21%, 16% for hypoxia, 8% for elevated liver function test values, and 6% for ARDS; 46% of patients required hospitalization.

**Differential Diagnosis**

On initial presentation, the differential diagnosis is extensive; however, it narrows with the occurrence of relapse. A history of possible soft tick exposure together with recurrent fever should suggest the diagnosis. Other conditions that initially may be considered include malaria, typhus, dengue, yellow fever, Colorado tick fever, and tularemia. Careful examination of blood smears, together with clinical data and other laboratory tests, aid in making the correct diagnosis.

**Diagnostic Testing**

The definitive diagnosis of relapsing fever depends on the demonstration of spirochetes in peripheral blood smears during a febrile episode. This is not a typical finding with other spirochetal diseases. In most cases, spirochetes are readily visible on a routine blood smear prepared with Wright or Giemsa stain. Thick or thin blood smears, such as those prepared for malaria evaluation, also are satisfactory. The organisms are seen within the plasma spaces between blood cells or may overlie the blood cells. Several organisms per high-power field typically are visible in smears from febrile patients with relapsing fever. Blood specimens for the smears should be obtained as the temperature curve swings up, and repeated samples may be required before a positive result is observed because sensitivity approaches only 70%.

Spirochetes also may be visible in wet mounts with the use of phase contrast microscopy. Culture, although it is the most sensitive diagnostic method available, requires a special medium, does not yield rapid results, and therefore is not commonly performed. Genus-specific PCR testing has been used successfully and may be higher in sensitivity than serology or blood smear, especially in the acute phase of disease. Serologic testing is available through public and private health facilities but is not useful for immediate diagnosis. Nonspecific laboratory findings may include mildly increased bilirubin and liver function levels, thrombocytopenia, and an elevated erythrocyte sedimentation rate.\[6\]

**Management**

Relapsing fever is effectively treated with tetracycline or erythromycin. Tetracycline should be avoided in children younger than 8 years and in pregnant women. Tetracycline or erythromycin should be given in an oral dose of 500 mg for 7 days; single-dose therapy is also effective. Other treatment regimens have been recommended, including doxycycline and chloramphenicol. Treatment with penicillin G has been associated with an increased rate of relapse. Success with ceftriaxone has been reported in a patient with relapsing fever who did not respond to penicillin. Prophylaxis with doxycycline for TBRF in exposed subjects in high-risk infested areas has been shown to be effective.

As many as one-third of patients experience a Jarisch-Herxheimer type of reaction during treatment with antibiotics. The reaction can be severe, especially with louseborne relapsing fever. This phenomenon may be related to release of high levels of cytokine intermediaries or endogenous opioids. Approximately 4 hours after antibiotic treatment, and coinciding with the clearance of spirochetes from the blood, the patient usually experiences an increase in temperature and severe rigors, accompanied by a drop in the leukocyte and platelet counts and onset of hypotension. Anticipation of this reaction is crucial because volume expansion with saline solution may be required to maintain the blood pressure; the reaction can be more threatening than the disease itself. Meptazinol, an opioid antagonist with agonist properties, has been proposed for use in treatment of this reaction.

The prognosis is good for treated patients with relapsing fever; approximately 93% achieve complete recovery. Poor prognostic signs include the presence of jaundice, high spirochete counts in the blood, and hypotension. Transplacental transmission can occur in infected pregnant women. Perinatal death of the fetus or infant and spontaneous abortions occur in nearly 50% of cases in pregnant women. Death is rare in TBRF and is limited to infants and older adults.

**TULAREMIA**

Tularemia was first characterized in 1837 by Soken, who described a febrile illness with generalized lymphadenopathy in people who had eaten infected rabbit meat. In 1912, McCoy first isolated *Bac terium tularense*, now known as *Francisella tularensis*, from rodents in Tulare County, California, giving rise to the name of the disease. Edward Francis, for whom the genus *Francisella* was later named, contributed much to the understanding of the bacteriology and epidemiology.

Tularemia occurs worldwide and is endemic between 30 and 71 degrees north latitude. The incidence of tularemia is low. There were 247 reported cases of tularemia in the United States between 2004 and 2005, although it is not a notifiable disease in all states. Tularemia has been seen in every state but is most common in the southwest central region (Arkansas, Louisiana, Oklahoma, Texas, and Mississippi). Of reported cases, 56% have come collectively from Missouri, Oklahoma, South Dakota, and Arkansas. It is more common in men than in women. Persons at increased risk for infection include hunters, trappers, butchers, agricultural workers, campers, sheep herders, mink farmers, and laboratory workers.

Ticks, lagomorphs (hares, rabbits), and rodents (mice, rats) are believed to be the most important sources of transmission to humans; however, the organism has been recovered from animals of more than 100 species. Significant epidemics have been linked to contact with a variety of them, including domestic cats.\[3\] In 2002, a large number of commercially distributed prairie dogs from Texas died of tularemia.

The ticks most commonly involved in transmission in the United States are the deer tick (*I. scapularis*), Lone Star tick (*A. americanum*), and dog tick (*D. variabilis*), all of which have been
associated with other tickborne illnesses. Whereas mosquitoes are major vectors in many European countries, horse fly and deer fly bites have been implicated in endemic situations in the United States. In 2007, an outbreak in Utah was associated with deer fly bites.1

Transmission to humans most commonly occurs through tick bites or handling of infected animals. It also can occur with ingestion of infected food or water, inhalation of dust or water aerosol, and insect bites. Nonimmune laboratory workers who work with F. tularensis can acquire the disease. Person to person transmission is rare. Tularemia has a bimodal prevalence in the United States; an increased incidence in May to August is associated with tickborne transmission, and a December to January peak is associated with hunting and skinning of infected mammals (primarily rabbits). F. tularensis has been found to coexist in reservoir populations harboring the agent responsible for Lyme disease. Eleven cases of pneumonic tularemia, found to be from aerosolization of contaminated vegetation clippings, were discovered in Martha's Vineyard, Massachusetts. Outside the United States, tularemia has been confirmed in hundreds of cases in Kosovo through rodent contamination of food. Sweden has reported a high number of cases, usually associated with aquatic environments and mosquitoes.13

Tularemia is manifested in different ways, depending on the portal of entry of the organism. The primary route of infection by F. tularensis is through the skin. Entry can occur through hair follicles or small cuts and abrasions that may be contaminated by exposure to an infected animal; tick exposure can also introduce the bacteria. Because the bacterium has not been isolated from the salivary glands of ticks, it is thought that they transmit the organism through their feces. Scratching after a tick bite introduces the infected feces into the skin. Inhalation or ingestion of the organism or transmission through the conjunctivae also can cause infection. The incubation period is approximately 2 to 6 days, depending on the size of the inoculum.

After penetration of the skin or epithelial membrane, the organism usually spreads to the regional lymph nodes. An erythematous tender papule develops at the primary infection site, followed by inflammation and skin ulceration. The regional nodes enlarge, necrose, and may rupture. The necrotic, purulent, painful lymph node is termed a bubo. In the ulceroglandular form of the infection, the organism may not spread farther than the regional lymph nodes. If the inoculum is sufficiently large or host defenses are inadequate, bacteremia ensues, with dissemination to phagocytic cells of the reticuloendothelial system. Pulmonary tularemia may result from inhalation of small-particle aerosols containing F. tularensis or from hemogenous dissemination. Small areas of localized pneumonitis are commonly seen, although chest radiographic findings are nonspecific; lobar consolidation or abscess formation is rare. Ulceroglandular tularemia occurs when the conjunctiva becomes infected from contact with material from an ulcer or contaminated finger. Typhoidal tularemia follows the systemic spread of F. tularensis from the oropharynx and probably the gastrointestinal tract when a large inoculum is swallowed.

**Clinical Features**

**Presentations**

Tularemia has six clinical presentations, depending on whether disease is localized to an entry site and its regional lymph nodes—ulceroglandular, glandular, oculoglandular, and oropharyngeal forms—or is more invasive and generalized—typhoidal and pulmonary forms.

**Ulcero glandular Tularemia.** This accounts for approximately 80% of cases. Typically, a skin lesion on an extremity at the site of primary inoculation begins as an erythematous papule, which then ulcerates 2 to 3 days later. The ulcer is slow to heal and often is still present when the subsequent regional lymphadenopathy and fever develop. The distribution of the regional adenopathy reflects the primary entry site; patients with tickborne tularemia usually have inguinal or femoral adenopathy, whereas those who acquire rabbit-associated tularemia have axillary or epitrochlear nodal involvement. Generalized lymphadenopathy also may be seen. On occasion, nodes suppurate and drain.

**Glandular Tularemia.** This is the second most common form. It is characterized by the development of lymphadenopathy (usually cervical) without an associated skin ulcer.

**Oculo glandular Tularemia.** This is seen in less than 2% of cases. It is characterized by unilateral conjunctivitis, with regional adenopathy involving preauricular lymph nodes.

**Oropharyngeal Tularemia.** This is manifested as severe exudative pharyngitis, with associated cervical lymphadenitis. It has been known to cause acute glaucoma.

**Typhoidal Tularemia.** This is a systemic form of the disease in which no obvious entry site can be found; it occurs in approximately 10% of cases. Only 10 to 50 organisms are required to induce disease; incubation time is 2 to 10 days. Symptoms and signs may include fever, chills, constipation or diarrhea, abdominal pain, and weight loss. A 30% to 60% case fatality rate is associated with untreated typhoidal tularemia.14

**Pulmonary Tularemia.** This has symptoms similar to those of other bacterial pneumonias—fever and chills, cough (usually nonproductive), substernal burning, dyspnea, malaise, and prostration. It may result from direct inhalation of aerosolized organisms or bacteremic spread from another site.

**Other Considerations**

Uncommon complications of tularemia include pericarditis, meningitis, endocarditis, peritonitis, appendicitis, perisplenitis, and osteomyelitis. Guillain–Barré syndrome associated with tularemia also has been reported.

Tularemia is one of the most widely studied diseases with respect to potential biologic warfare. The United States developed an aerosolized form in the 1950s, and the Japanese allegedly contaminated prisoners with the disease in the 1930s. It was removed from the national list of notifiable diseases in 1995 but then was reinstated in view of the heightened biologic weapons threat. It is classified by the CDC as one of the six category A critical biologic diseases. An aerosolized form of the bacterium would be the most likely delivery mechanism used in biologic warfare. With the release of aerosolized particles, disease would be manifested clinically as acute fever, progressive pneumonia, pleuritis, and hilar lymphadenopathy, beginning as early as 3 to 5 days after delivery. The mortality rate for untreated tularemia in general ranges from 5% to 30%, but the rate for the pulmonary form can reach 60%.15

With appropriate antibiotic treatment, death is rare (mortality rate < 1%). Only approximately 55% of emergency departments (EDs) have been adequately educated on the recognition of and preparedness for tularemia.

**Diagnostic Testing**

The diagnosis of tularemia is based on clinical findings and serologic testing. Antibody titers begin to rise approximately 7 to 10 days after exposure and peak in 3 to 4 weeks. In a patient with a clinical presentation suggesting tularemia, an antibody titer of
1:160 or higher in a single specimen is diagnostic. Confirmatory evidence is provided by a fourfold or greater rise in titer in a second sample obtained 2 weeks later. Unfortunately, titers of IgG and IgM can continue to be high for up to 10 years, and cell-mediated immunity can be maintained for up to 25 years. Rapid testing with PCR assay is available, and point of care analysis using an immunochromatographic approach has proven useful in testing water sources.

As for most infectious organisms, culture is the gold standard for diagnosis; however, aspiration of affected lymph nodes for culture is not routinely recommended because of the associated risk to laboratory personnel. If tularemia is suspected, the laboratory should be alerted so that appropriate precautions can be taken in specimen handling and enriched culture medium can be used.

**Management**

Isolation of patients with tularemia is not required. Streptomycin is the drug of choice for the treatment of all forms of tularemia, but is not widely available. When given intramuscularly in a dose of 30 to 40 mg/kg/day bid, streptomycin usually produces symptomatic improvement and resolution of fever in 1 to 2 days. After the third treatment day, half of the dose is given for a total course of 7 to 14 days. With this regimen, relapses are unusual.

Gentamicin is effective for treatment, especially in children (3 to 5 mg/kg/day for 10 to 14 days), and is more readily available. Tetracycline and chloramphenicol are also effective; however, the risk of relapse is greater than that associated with the aminoglycosides. Imipenem-cilastatin, an antibiotic without nephrotoxicity, has been used successfully to treat pulmonary tularemia in a patient with acute renal failure. Ceftriaxone is not effective against *F. tularensis* infections. Prophylaxis for possible exposure requires doxycycline, 100 mg bid for 14 days. Doxycycline or ciprofloxacin prophylaxis is recommended for a large biologic attack. Ulcers and tender lymph nodes usually heal within 7 to 10 days; however, enlarged nodes occasionally develop into fluctuant sterile buboes, requiring incision and drainage after completion of the course of antibiotics. The unique ability of *F. tularensis* to attenuate host inflammatory responses has been emerging as a basis for research investigating the use of immunomodulatory agents or antibodies for adjunctive treatment. There continues to be no approved vaccine for tularemia. Because of recent interest in biologic warfare, however, research on tularemia vaccines has resurfaced.

**ROCKY MOUNTAIN SPOTTED FEVER**

Rocky Mountain spotted fever (RMSF) is an acute, febrile, systemic tickborne illness caused by *Rickettsia rickettsii*. The genus *Rickettsia* is divided into the spotted fever group and typhus group. *R. rickettsii* is considered the typical representative of the spotted fever group. Twenty-six species now exist.

RMSF is found in North, South, and Central America and is a nationally reportable disease. All cases are to be registered with the respective state department. As of 2010, reported cases of RMSF are categorized in the broader name of spotted fever group or typhus group. *R. rickettsii* is considered the typical representative of the spotted fever group. Twenty-six species now exist. The number of reported cases in the United States more than tripled between 2000 and 2007, especially in suburban areas. The increase during this period was thought to be due to more widespread use of ELISA. Use of the assay has also resulted in a significantly lower case fatality rate, which could be related to the high cross-reactivity of serologic tests with more benign rickettsioses. Higher awareness and more aggressive empirical treatment of RMSF might also have contributed to the decreased fatality rate. The number of reported spotted fever cases in the United States rose 9% in 2010, which included all spotted fever rickettsioses, not just RMSF, in accordance with the surveillance changes mentioned. Another rare rickettsiosis that emerged in North America in 2004 was caused by *Rickettsia parkeri*, transmitted through the Gulf Coast tick, *Amblyomma maculatum*. It is distinguished from RMSF by sometimes causing eschars or a vesicular rash.

RMSF ranges in clinical severity from mild or even subclinical illness to a fulminating disease, with vascular collapse and death within several days of onset. It is the only rickettsiosis still associated with significant mortality, causing approximately 40 deaths in the United States each year, with a mortality rate ranging from 3% to 5%, despite appropriate treatment. Before tetracycline and chloramphenicol were available, death occurred in as many as 30% of cases in the 1930s. The highest mortality rates occur in patients between the ages 5 and 9 years or older than 70

---

**BOX 126.1**

**Diagnostic Criteria for Spotted Fever Rickettsiosis (Rickettsia spp.)**

- **Clinical criteria**
  - Any reported fever and one or more of the following: rash, eschar, headache, myalgia, anemia, thrombocytopenia, or hepatic transaminase level elevation

- **Laboratory-confirmed**
  - Serologic evidence of a fourfold change in immunoglobulin G (IgG)–specific antibody titer reactive with *Rickettsia rickettsii* or other spotted fever group antigen by indirect immunofluorescence assay (IFA) between paired serum specimens (one taken in the first week of illness and a second 2 to 4 weeks later) or
  - Detection of *R. rickettsii* or other spotted fever group DNA in a clinical specimen via amplification of a specific target by PCR assay, or
  - Demonstration of spotted fever group antigen in a biopsy or autopsy specimen by immunohistochemistry (IHC), or
  - Isolation of *R. rickettsii* or other spotted fever group Rickettsia from a clinical specimen in cell culture

- **Laboratory-supportive**
  - Has serologic evidence of elevated IgG or immunoglobulin M (IgM) antibody reactive with *R. rickettsii* or other spotted fever group antigen by IFA, enzyme-linked immunosorbent assay (ELISA), dot ELISA, or latex agglutination

- **Exposure**
  - Exposure is defined as having been in a potential tick habitat within the 14 days preceding the onset of symptoms. The patient’s occupation should be recorded if relevant to exposure. A history of a tick bite is not required.

- **Case classification**
  - Suspected: A case with laboratory evidence of past or present infection but no clinical information available (eg, laboratory report)
  - Probable: A clinically compatible case (meets clinical evidence criteria) that has supportive laboratory results
  - Confirmed: A clinically compatible case (meets clinical evidence criteria) that is laboratory-confirmed

*NOTE: Current commercially available ELISA tests are not quantitative, cannot be used to evaluate changes in antibody titer, and hence are not useful for serologic confirmation. IFA tests are not strongly supported for use in the serodiagnosis of acute disease because the response might not be specific for the agent (resulting in false-positives) and the IgM response might be persistent. Complement fixation (CF) tests and older test methods are neither readily available nor commonly used. CDC uses in-house IFA IgG testing (cutoff ≥ 1:64), preferring simultaneous testing of paired specimens, and does not use IgM results for routine diagnostic testing.*
years, among Native Americans, and among immunosuppressed patients. In the South Atlantic United States, mortality reaches 9% in patients older than 70 years. The median time between onset of illness and death is 9.5 days, whereas death occurs in hospitalized patients in a median time of 3 days.

The recorded history of RMSF suggests that the disease was present at least before the European settlement of western North America among inhabitants of wooded Rocky Mountain regions. Early terms used to name the disease included tick fever and black measles. In 1899, RMSF was described as “an acute, endemic, noncontagious but probably infectious, febrile disease, characterized by a continuous moderately high fever, severe arthritic and muscle pains, and a profuse petechial or purpuric eruption in the skin, appearing first on the ankles, wrists, and forehead, but rapidly spreading to all parts of the body.” In 1906, the causative organism, R. rickettsii, was identified by Howard T. Ricketts, who also described the importance of the tick vector in transmission to humans.

Although RMSF was first described in Montana and Idaho, it is now relatively rare in the Rocky Mountain states. Endemic in all 48 contiguous states except Maine, the disease continues to be most prevalent in the southeastern United States. RMSF has been reported in Canada, Central America, Mexico, and South America but never outside the Western Hemisphere. In 1987, four cases of RMSF were reported among residents of the Bronx in New York City; none of the affected persons had recently traveled to an area known for endemic disease, raising the possibility that other urban foci of RMSF may exist.

RMSF also tends to be focally endemic, with clustering of cases within a larger endemic area that may correspond to islands of infected ticks. These areas, ecologically distinct from surrounding areas, may be ideally suited to ticks; they usually consist of wild open fields, deciduous forests with thick ground cover and poor water drainage, or uncultivated areas. Geographic clusters of severe disease have been reported.

Areas with frequent occurrence of RMSF (Oklahoma, North and South Carolina, Tennessee, Pennsylvania, Missouri, Arkansas), an infectivity rate of 2% to 15% of the tick population has been reported. North Carolina and Oklahoma carry the highest incidence rates (35% of all cases) for RMSF.

R. rickettsii organisms are obligate intracellular bacteria with tropism for human endothelial cells. They often occur in pairs and possess a cell wall similar in structure and chemical composition to that of gram-negative bacteria. R. rickettsii contain RNA and DNA and, in contrast with other rickettsial organisms, can invade the nucleus as well as the cytoplasm.

The American dog tick, Dermacentor variabilis, and the Rocky Mountain wood tick, Dermacentor andersoni, have been the vectors responsible for human RMSF cases in the United States to date. However, the common brown dog tick, Rhipicephalus sanguineus, has emerged as a third vector. R. sanguineus has been the main RMSF vector in Mexico and Central America. Amblyomma imitator, in the genus of the Lone Star tick, has been implicated as yet another vector because R. rickettsii has been found in its eggs.

Ticks feed on virtually any available warm-blooded animal and human; the occurrence of R. rickettsii in the United States does not depend on the presence of any given order of mammal. Domestic dogs infected with R. rickettsii can demonstrate clinical illness similar to that seen in humans. Although dogs do not play an important role in the amplification cycle of RMSF, they can serve as a conduit for infected ticks, carrying them into close contact with pet owners. Dogs may serve as sentinels for RMSF in humans. A high prevalence of rickettsial antibodies in stray dogs in Arizona was thought to be a major factor in the 70 cases and 8 deaths from RMSF reported there between 2003 and 2008.

It has been speculated that the reason Native Americans have a fourfold greater incidence and case fatality rate than other ethnic groups is a result of their more frequent exposure to free-roaming dogs. The deadliest spotted fever, Brazilian spotted fever, is also caused by R. rickettsii. The capybara, a common mammal in Brazil, appears to be the main reservoir through the vector tick Amblyomma cajennense.

Pathophysiology
After introduction of R. rickettsii into the host by the tick vector, the organisms invade and multiply in the vascular endothelial cells. They then enter deeper areas of the vessel walls and infect vascular smooth muscle. Rickettsial organisms move from cell to cell by actin-based motility. Damage to endothelial cells not only exposes subendothelium but also releases tissue plasminogen activator and von Willebrand factor, thereby causing microhemorrhage, microthrombosis formation, and increased vascular permeability. In addition, antibody forms, with antigen activating the complement system (type III immune response), and a cellular response is recruited.

These widespread vascular lesions form the basis for most of the clinical features associated with RMSF. Hypotension, edema, and increased extravascular fluid space result from the increased small-vessel permeability. The early rash results from the vasculitis and associated changes in permeability; later petechial and hemorrhagic lesions are secondary to the vasculitis and thrombocytopenia. Microinfarcts and focal lesions develop in various organs, including the brain, heart, lungs, kidneys, adrenal glands, liver, and spleen. Rickettsial encephalitis and diffuse microinfarcts are usual features of central nervous system involvement. An interstitial pneumonia caused by direct lung invasion by the organism may occur, and ARDS can ensue. Acute renal failure and hypovolemic shock, the primary causes of death, can occur as early as the second week of illness.

Clinical Features
Children from 5 to 9 years of age are the most common victims of RMSF. Two-thirds of all cases are in children younger than 15 years. More than 90% present with a fever and rash. A history of tick bite or presence in possible tick-infested areas is elicited in 60% to 70% of all patients with RMSF; although only 49% of the pediatric population reports a bite. The incubation period ranges from 2 to 14 days, with a mean of 7 days. A short incubation period may indicate a more serious infection. Factors that bring higher risk of death include delayed onset of rash, glucose-6-phosphate dehydrogenase deficiency, hepatomegaly, neurologic deficits, renal insufficiency, increased period between symptoms and antibiotic treatment, and lack of tick bite history.

Onset of symptoms usually is generally abrupt but may be gradual in approximately one-third of patients. Early symptoms are nonspecific and similar to those of many acute infectious diseases, making early diagnosis difficult. Typical patients experience sudden onset of fever, severe headache, myalgias, prostration, nausea, and vomiting. Tenderness may be noted in large muscle groups (Table 126.4). As many as 80% of patients may have gastrointestinal symptoms secondary to myositis of the abdominal wall. Fever (temperature usually > 102° F [39° C]) is nearly always present during the first 2 to 3 days of illness and may precede other signs by 1 week or more. On occasion, the onset of illness is mild, with lethargy, headache, anorexia, and low-grade
Involvement of the scrotum or vulva can be an evasive clue. Rash on the palms and soles is reported in approximately 50% of cases, referred to as Rocky Mountain spotted fever. In addition, the rash reportedly is absent in 4% to 16% of laboratory-confirmed cases, more recent data have shown that it is found in up to 45% of children with the disease. An extreme complication of RMSF is gangrene, which probably is induced by small-vessel occlusion.

Cutaneous Manifestations

Vasculitis secondary to rickettsial invasion of vascular endothelial cells causes the rash commonly associated with RMSF; however, the rash reportedly is absent in 4% to 16% of laboratory-confirmed cases, referred to as Rocky Mountain spotted fever. In addition, the rash may go unnoticed in dark-skinned patients. It usually appears on the third to fifth febrile day but can emerge as early as the second and as late as the sixth day. The initial lesions generally are restricted to the ankles and wrists, spreading to the palms and soles. The rash then spreads centripetally to the forearms, arms, legs, thighs, and trunk. The face can be involved, although it is usually spared. Despite the common belief that the palms and soles are critical for diagnosis, they are not consistently involved; rash on the palms and soles is reported in approximately 50% of cases. Involvement of the scrotum or vulva can be an evasive clue for RMSF. The rash of RMSF typically begins as 1- to 5-mm blanchable pink to bright red discrete macules that may be pruritic (see Fig. 126.7). At this initial stage, the lesions fade when pressure is applied and are not palpable. A warm compress applied to the area enhances the rash. After 6 to 12 hours, the rash spreads centripetally. After 2 to 3 days, the rash becomes maculopapular and changes to a deeper red; at this stage, skin changes can be appreciated on light palpation. By approximately the fourth day, the rash becomes petechial and no longer fades with applied pressure. Applying tourniquets for several minutes or taking the blood pressure may cause additional petechiae to form distal to the site of occlusion (Rumpel-Leede phenomenon). The lesions occasionally coalesce to form large ecchymotic areas that may slough and form indolent ulcers (Fig. 126.8).

Prompt institution of specific therapy can cause the initial nonfixed lesions to disappear rapidly, unlike the later fixed lesions. Patients who have had the typical rash may exhibit brownish discolorations at the site during the convalescent period.

Cardiopulmonary Manifestations

Echocardiographic evidence of decreased left ventricular contractility secondary to myocarditis is commonly seen and often is detectable even before clinical signs of RMSF appear. Clinical manifestations of left ventricular dysfunction are uncommon, however, and hypotension and pulmonary edema, when present, usually have noncardiogenic causes. Chest radiographs may demonstrate cardiac enlargement. Electrocardiographic changes include low-voltage, nonspecific ST-T changes, first-degree AV block, dysrhythmias (eg, sinus and nodal tachycardia, paroxysmal atrial tachycardia, atrial fibrillation), and left ventricular hypertrophy. Most cardiac abnormalities are transient, but persistent echocardiographic changes have been described. Decreased systolic function, elevated serum cardiac markers, no finding of vascular lesions, and a fourfold rise in antibody titers are consistent with myocarditis from RMSF.

Interstitial pneumonitis and increased pulmonary capillary permeability may result from infection of the pulmonary capillaries with rickettsiae. Nonproductive cough and dyspnea secondary to pneumonitis are sometimes seen on presentation. Chest radiographic abnormalities are identified in approximately 25% of patients. These abnormalities include interstitial infiltrates, patchy alveolar infiltrates, pleural effusions, and cardiomegaly with pulmonary edema. Pulmonary consolidation is rare. In severe cases, progression to noncardiogenic pulmonary edema and ARDS may occur.

Neurologic Manifestations

Neurologic manifestations of RMSF range from mild headache and lethargy to seizures and coma. Acute disseminated encephalomyelitis has been described. Headache, generally severe, is common, occurring in 50% to 90% of cases. Meningismus is present in 16% to 29% of patients. The CSF may be normal or show a slight protein elevation and pleocytosis of lymphocytes and polymorphonuclear cells (usually 8 to 35 cells/mL). The CSF glucose level and opening pressure usually are normal. Resolution of eosinophilic meningitis during RMSF after appropriate antibiotic treatment has been reported. Less than 40% of patients have a positive CSF finding.

Cerebral thrombovasculitis may cause focal neurologic deficits, which usually are transient. Seizures can occur, especially during the acute phase of the illness. Generalized cerebral dysfunction ranging from lethargy to coma can occur secondary to systemic toxicity (eg, fever, hypotension, hyponatremia) or vasculitic lesions involving the central nervous system. Coma is a late finding in patients with severe disease and is seen in less than 10%
Tickborne Illnesses

fever, leptospirosis, murine typhus, and epidemic typhus. *R. parkeri* rickettsiosis should be considered.

Diagnostic Testing

Most immediately available laboratory tests provide little help in the diagnosis of RMSF. Early in the course of the illness, the

Differential Diagnosis

Delayed diagnosis or misdiagnosis is the principal reason for the historically significant mortality associated with RMSF. Clinical diagnosis is difficult, especially early in the course of the illness, because of its nonspecific presentation. For avoidable deaths to be prevented, a diagnosis of RMSF should be considered in any patient with an unexplained febrile illness, with or without a rash and headache, even in the absence of a history of tick bite or travel to an area known to be endemic for the disease. The emergency clinician should remember to ask routinely about recent tick bites, especially when assessing children with unexplained febrile illness, because parents do not always spontaneously provide this important information. An atypical presentation or manifestation of RMSF also should be considered during the differential diagnosis, including the following: (1) absence of a rash (Rocky Mountain spotless fever) or late appearance of a rash (Fig. 126.9); (2) predominant gastrointestinal features or abdominal pain suggestive of an acute condition in the abdomen; (3) cough and pulmonary congestion suggestive of pneumonitis; and (4) meningismus suggestive of viral meningitis. A presumptive diagnosis is advised, with the initiation of specific therapy, well before specific confirmatory laboratory values are available.

A wide variety of other infections with similar exanthems can be confused with RMSF. The most common include meningococcal infection, measles (rubeola) and atypical measles, gonococemia, infectious mononucleosis, toxic shock syndrome, and enteroviral infections. Less common diseases include dengue.

Fig. 126.9. Late appearance of the rash of Rocky Mountain spotted fever on the lower extremity. (Courtesy Dr. Theodore Woodward.)

fever, leptospirosis, murine typhus, and epidemic typhus. *R. parkeri* rickettsiosis should be considered.

Diagnostic Testing

Most immediately available laboratory tests provide little help in the diagnosis of RMSF. Early in the course of the illness, the
diagnosis is based primarily on clinical evidence, so epidemiologic features should be correlated with clinical signs and symptoms. The initial presentation of RMSF is similar to that of many acute febrile infectious diseases, and almost invariably a therapeutic decision must be made on clinical grounds alone, without the luxury of confirmatory laboratory evidence. Abnormalities such as thrombocytopenia, hyponatremia, and acute renal failure may be detected by routine laboratory tests, but they are nonspecific and unhelpful diagnostically. Up to 30% of patients present with anemia. A definitive diagnosis of RMSF requires positive results on one or more of several tests—serologic study, skin biopsy, or direct isolation and identification of the organism (see Box 126.1).

Skin Biopsy

Identification by immunofluorescent assay (IFA) and immunoperoxidase staining of R. rickettsii in biopsy specimens of the rash from patients with suspected RMSF are the best rapid diagnostic tests currently available. In experienced laboratories, the diagnosis of RMSF can be confirmed as soon as 4 hours after the specimen is obtained. The organisms can be detected as early as day 3 of clinical illness and as late as day 10. Unfortunately, this technique can be used only when a rash is visible for accurate localization of the biopsy site. Biopsy specimens generally are obtained with a 3-mm punch in the center of the skin lesion. Immunofluorescent demonstration of rickettsiae in frozen sections of skin biopsy specimens has a sensitivity of 70%. Results of immunohistochemical staining of tissues at autopsy were positive in all fatal cases in one study, whereas IFA results were negative in most cases. Failure to obtain a biopsy specimen of a rickettsial cutaneous lesion or failure to obtain sections through its center is associated with false-negative results. Treatment with antirickettsial drugs for 24 hours does not appreciably alter the sensitivity of the test; however, after 48 hours, rickettsiae are substantially reduced in number.

Serologic Studies

Rickettsial infection can be confirmed by demonstration of an antibody rise in paired sera. Even with the most sensitive serologic tests, however, elevations in antibody titer do not occur until approximately 5 to 7 days after the onset of initial symptoms. Accordingly, serodiagnosis is retrospective. It is achieved by comparing acute serum, which typically yields negative findings, with convalescent serum, which yields positive results for antibodies. The indirect IFA generally is considered to be the reference standard for RMSF diagnosis and is the test currently used by the CDC and most state public health laboratories. It has a high specificity and sensitivity (94%). IFA can be used to detect IgG or IgM antibodies. An RMSF latex agglutination test that reportedly gives a sensitivity (94%). IFA can be used to detect IgG or IgM anti-

A prior study has shown a 12% seroprevalence, with antibody titers of 1:64 or higher, in the pediatric population in the southeastern and south central regions of the United States. Accordingly, clinical correlation with titers in these regions is critical. Convalescent-stage blood samples are best obtained 2 to 3 weeks after the onset of clinical illness. Antibiotic therapy does not affect the time of appearance of antibodies or their ultimate titer if this treatment is begun several days after the onset of illness. However, if antibiotic therapy is initiated earlier in the course of the illness, the rise in titers can be delayed for 4 weeks or more. Under these circumstances, antibody titers should be tested again at 4 to 6 weeks after the onset of illness. Nested PCR testing with a turnaround time between 1 and 2 days has been used but is not specific for individual rickettsial species. Real-time PCR assays that can be completed in 1 hour and are 100% specific for RMSF have been developed but are not readily available.12

Isolation of Organism

For most pathogenic infections, the standard diagnostic criterion is isolation and identification of the causative organism from the patient’s blood or tissues. This is seldom attempted in rickettsioses, however, because the isolation procedures are time-consuming, expensive, and hazardous to laboratory personnel. In addition, primary isolation of rickettsiae by inoculation in the yolk sac of a chick embryo usually fails because of the small number of organisms in the patient’s blood.

Management

Treatment of RMSF consists of antibiotic therapy, supportive care, and possibly administration of steroids. An understanding of the underlying pathophysiologic changes and appreciation of the systemic complications that can occur in the patient afflicted with RMSF are necessary for the formulation of a balanced therapeutic regimen. The course of the disease can be complicated by circulatory collapse, coma, renal failure, and electrolyte imbalances. Although these complications are often absent in the mildly ill patient, for whom antibiotic therapy alone usually suffices, they should be anticipated in the seriously ill patient, especially if the patient is first seen late in the disease course.

The most important factor contributing to the persistent case fatality rate of 5% is delayed administration of specific antibiotic therapy. Without appropriate treatment, the fatality rate rises to 25%. For a select group of early-stage, mildly ill patients, outpatient therapy with oral antibiotics can be successful if the patient is reliable and close follow-up observation is arranged. More severely ill patients in whom the diagnosis is uncertain should be hospitalized for the administration of IV antibiotics.

Supportive Care

Major complications of RMSF, such as shock, congestive heart failure, disseminated intravascular coagulation, and ARDS, should be anticipated and standard supportive measures instituted when appropriate. Circulatory collapse is common in patients with severe illness and is a major contributor to morbidity and mortality in RMSF. Hypotension unresponsive to fluid administration may require the use of vasopressors, such as dopamine. In the critically ill patient with widespread vasculitis, however, a delicate balance exists between maintenance of effective circulating volume and excessive leakage of fluids into the tissues, including the lungs and brain. Under these circumstances, the excessive administration of IV fluids can be catastrophic. Isolation of the patient is unnecessary unless the diagnosis is still uncertain and other highly communicable illnesses, such as meningococcemia and measles, have not been excluded.

Antibiotics

Antibiotic therapy is most effective when initiated during the early stages of disease, coincident with the initial appearance of the rash. Although data from randomized clinical trials about antibiotic selection for RMSF are lacking, doxycycline is still widely regarded as the therapeutic agent of choice for most patients, including children.33 Chloramphenicol should be considered only for patients in whom tetracyclines have caused significant adverse events and for pregnant women, except those who are near term. The recommended doses of doxycycline and chloramphenicol are summarized in Table 126.5.
The American Academy of Pediatrics and CDC recommend doxycycline as the agent of choice for treatment of RMSF in children of all ages. The risk of cosmetically perceptible tooth staining appears to be small for a single course of treatment and is subordinate to the potential lethality of this illness.

The effectiveness of therapy depends on the duration of therapy and interval between the onset of illness and the initiation of therapy. Treatment should begin as early as possible and continue for 7 to 10 days or until the patient is afebrile for 2 to 5 days. Patients who are clinically ill should be hospitalized for parenteral antibiotic treatment. Response to treatment, as manifested by decreasing fever and subsiding rash, generally occurs 36 to 48 hours after antibiotic therapy is begun. Resistance to chloramphenicol or tetracyclines has not been reported. Penicillin, erythromycin, cephalosporins, aminoglycosides, clindamycin, and sulfonamides are ineffective against RMSF. In fact, empirical use of these agents for presumed bacterial infections could permit progression of the illness.

Symptom overlap between early meningococcal infection and RMSF frequently leads to both diagnoses being considered simultaneously. After blood and CSF culture specimens are obtained, empirical antibiotic coverage with ceftriaxone plus doxycycline should be administered.

On occasion, secondary bacterial infection from the RMSF rash may occur. Although sulfonamides have become a mainstay for the empirical treatment of MRSA skin infections, the use of these agents should be avoided in RMSF patients because their mechanism of inhibiting p-aminobenzoic acid may worsen the primary RMSF infection. The role of the new quinolones as potential replacements for doxycycline and chloramphenicol in the treatment of RMSF is as yet unproved. At present, no vaccine is available for RMSF.

Corticosteroids

The use of steroids in RMSF is controversial and is not routinely recommended. However, these agents should be considered for severe cases of RMSF complicated by extensive vasculitis, encephalitis, and cerebral edema. In these critically ill patients, short-term, high-dose steroid therapy is recommended, along with concomitant specific antibiotic therapy.

Q FEVER

Q fever was first described in 1937 in Australia as an occupational disease of abattoir workers and dairy farmers. Cattle, sheep, goats, and ticks are the primary reservoirs of the causative rickettsia, Coxiella burnetii, but many other species may be infected. The disease is now endemic worldwide, although it is rare in Scandinavian countries. The southern area of the Netherlands experienced a serious outbreak and reported more than 4000 cases since 2007 and 500 cases, with 11 deaths, in 2010 alone. France and Australia have significantly more cases than the United States. In the United States, the Midwest and California have had the highest incidences of Q fever. More than 30 cases have been seen in US military personnel deployed in Iraq and Afghanistan. Approximately 80% of cases of Q fever occur in males.

**Pathophysiology**

C. burnetii is extremely infectious for humans and animals; a single inhaled organism is sufficient to initiate infection in guinea pigs and probably in humans as well. The Q fever rickettsiae are extremely resistant to desiccation and physical and chemical agents and can survive for long periods in an inanimate environment. Consequently, it is classified as a category B biologic warfare agent by the CDC and has been a nationally notifiable disease since 1999. The organism’s infectivity and estimated casualty rate have been judged to be comparable with those of anthrax. Humans most commonly are infected by inhalation of aerosolized particles from contaminated environments. Patients with Q fever rarely can recall a history of tick bite. The Rocky Mountain wood tick, D. andersoni, is the only currently known tick vector.

**Clinical Features**

The incubation period of Q fever ranges from 14 to 39 days, with an average of 20 days. Up to 60% of initial infections are asymptomatic. The acute form of the disease includes clinical manifestations such as severe retrobulbar headache, fever with temperatures to 40°C (104°F) or higher, shaking chills, general malaise, myalgia, and chest pain. Although Q fever is widely regarded as primarily a respiratory disease, the reported incidence of pulmonary involvement varies, ranging from 0% to 90%. The reasons for this reported variation are unclear, but explanations include geographic strain variation, plasmids that may regulate virulence, geographic strain variation, plasmids that may regulate virulence, and strain variation. Plasmids that may regulate virulence, and source, route, and dose of the agent. Hepatic involvement may be common, but liver dysfunction is usually minimal. Osteomyelitis in children, acute renal failure, and lymphocytic meningitis secondary to C. burnetii have been described.

Q fever also may be a chronic infection, with or without an antecedent acute episode. Clinical syndromes with the chronic form of the disease include granulomatous hepatitis and culture-negative endocarditis. Endocarditis has been documented in up to 68% of patients with chronic Q fever; the mortality rate for this group approaches 25%. Q fever accounts for 3% to 5% of all cases of endocarditis. Most patients with Q fever in whom endocarditis develops have a history of valvular heart disease, particularly affecting the aortic valve. These patients should be especially cognizant of the potential hazards of Q fever infection and should be restricted from certain at-risk occupational settings. Patients with aneurysms and vascular grafts also are at risk.
Human fetal demise and deaths have been attributed to *C. burnetii* infection. Persons infected with human immunodeficiency virus (HIV) are at increased risk for contraction of Q fever.

### Diagnostic Testing

The diagnosis of Q fever should be suspected in any patient with a severe febrile illness without obvious cause, especially someone who has had recent contact with sheep, cattle, goats, or animal byproducts. Because of the laboratory hazards associated with the cultivation of Q fever rickettsiae, isolation of *C. burnetii* is not recommended for routine diagnosis. Rather, serologic studies such as IFA and ELISA are the preferred diagnostic tests, but the results are not identifiable until 2 to 3 weeks after the onset of illness.

*C. burnetii* displays an antigenic phase variation. In patients with acute Q fever, phase II antibodies dominate the humoral immune response and are detectable by the second week of illness, whereas phase I antibodies are prominent only in patients with chronic Q fever. Confirmation of a Q fever case requires (1) a fourfold increase in IgG titers between acute and convalescent samples or the presence of IgM phase II antibodies, (2) a positive PCR test result, (3) the culture of *C. burnetii* from a clinical specimen, or (4) the positive immunostaining of the organism in tissue. Measurement of IgA and IgG together has been useful in the diagnosis of endocarditis. The finding of granulomatous changes on bone marrow biopsy can be characteristic of Q fever in patients with osteomyelitis.

### Management

Uncomplicated acute Q fever is treated with doxycycline (200 mg once daily for 2–3 weeks). Acute disease with concomitant valvular heart disease is treated with doxycycline (200 mg once daily) plus hydroxychloroquine (600 mg once daily) for 1 year. Chronic sufferers should be given the same regimen for 1.5 to 3 years. Combination therapy with doxycycline and hydroxychloroquine has been shown to be effective for treatment of endocarditis in HIV-infected patients. Strong evidence has recommended combination therapy for endocarditis for 18 and 24 months in patients with osteomyelitis.

Cotrimoxazole is the recommended alternative treatment. Quinolones, some macrolides, and rifampin can afford considerable protection to slaughterhouse and abattoir workers. Reservoirs include the white-tailed deer and certain rodents. 

C. burnetii is not the only member of the genus *Anaplasma*—hence, the revised name. Both genera, *Ehrlichia* and *Anaplasma*, are now considered to be in the tribe *Ehrlichieae*, family *Anaplasmataceae*, but are still collectively referred to as being in the group of diseases called ehrlichioses. Before 1986, *Ehrlichia sennetsu* was the only member of the genus of these organisms thought to infect humans, having been isolated in Japan in 1954 as the causative agent of sennetsu fever, a mononucleosis-like illness. A third species, *Ehrlichia ewingii*, has been shown to cause human disease in the United States. HME was discovered in 1986 and HGA (previously human granulocytic ehrlichiosis) in 1994.

### Pathophysiology

The causative agents in the ehrlichioses are gram-negative, obligate, intracellular, rickettsia-like cocobacilli. Transmitted from the midgut and salivary glands of their tick vectors, these organisms reside in specific circulating leukocytes in human and other mammalian hosts. Reservoirs include the white-tailed deer and white-footed mouse. *Ehrlichia canis* is the common pathogenic species in dogs. The species *Ehrlichia equi* has been isolated in...
California elk. HME, transmitted by the Lone Star tick, *A. americanum*, is caused by the organism *E. chaffeensis* (named for Fort Chaffee, Arkansas), which invades monocytes. *Ehrlichia ewingii* and *Ehrlichia muris* are also now known to be causative organisms.

*E. chaffeensis* has been isolated from *I. pacificus* ticks in California. *A. phagocytophilum* invades neutrophils (granulocytes), causing HGA and, in the United States, is transmitted by the black-legged tick, *I. scapularis*, and its West Coast counterpart, the western black-legged tick, *I. pacificus*. Deer, elk, and wild rodents are the main reservoirs for *Anaplasmata*. Both ticks also are the vectors for Lyme disease. *A. phagocytophilum* has been detected in significant numbers in various *Ixodes* human tick species in mainland Portugal, Italy, and Japan. Two cases of HGA in Italy have been reported.

**Clinical Features**

The clinical presentations of HME and HGA are similar and, for case management, it is not necessary to differentiate between the two illnesses. The average time to onset of symptoms (for HME) from tick discovery is 9 days but ranges from 0 to 34 days. More than 90% of patients with HME report a history of tick bite or tick exposure. Ehrlichiosis characteristically is manifested with abrupt onset of fever, headache, myalgia, and shaking chills. Other, less frequent manifestations include nausea, vomiting, diarrhea, abdominal pain, cough, and confusion. Leukopenia, thrombocytopenia, and elevated liver function test values can be seen in 50% to 90% of patients.

Rashes occur in approximately one-third of patients with HME but in only 2% to 11% of those with HGA. In a small series of pediatric patients (average age, 7.4 years) with HME, a rash rate of 67% was found. Most of these patients suffered permanent cognitive or other neurologic damage.

Ehrlichiosis (HME) also has been associated with optic neuritis, ARDS, meningitis, pancarditis, renal failure, and disseminated intravascular coagulation have been associated with the ehrlichioses. Case fatality rates vary between studies but range from 0.5% to 3% for both diseases, with HGA usually reported as the lower of the two. Approximately 45% of patients with HGA require hospitalization, although almost all recover without residual problems. HME has been associated with hemophagocytic lymphohistiocytosis.

**Diagnostic Testing**

For HME and HGA, the initial diagnosis is based largely on clinical presentation. With most tests, the diagnosis will be retrospective; results are rarely available immediately. The most common mode of diagnosis is confirmation of acute and convalescent antibodies with IFA. Enzyme immunoassay and confirmatory tests with Western blot have been developed but are not readily available. They provide only positive or negative results without titers. PCR testing for DNA fragments, although also not as readily available in most institutions, probably is most reliable in the acute phase of illness (at 1 week after onset of symptoms). Diagnostic serologic testing is available at the CDC through state health departments.

Laboratory criteria required in the CDC’s 2008 case definition to establish the presence of HME or HGA include detection of *E. chaffeensis* or *A. phagocytophilum*, respectively, through the use of the following diagnostic tests: (1) fourfold change in antibody titer to the organism antigen by IFA in paired serum samples; (2) positive result on PCR assay and confirmation of organism-specific DNA; (3) identification of morulae in leukocytes and a positive titer to the organism antigen; (4) immunostaining of the organism’s antigen in a biopsy or autopsy specimen; or (5) culture of the organism from a clinical specimen. All tests require compatible clinical findings. Most patients with acute ehrlichiosis have antibody titers higher than 1:160.46

Cytopenia and abnormal liver function usually resolve after the acute phase of illness by 14 to 28 days. Microscopic identification of mulberry-like clusters (morulae) inside leukocytes on peripheral blood smears is helpful (Fig. 126.11), but this finding usually has disappeared after the first week of illness with HGA, especially if the patient has been treated with doxycycline. Cultures take up to 2 weeks to grow the organisms.

**Management**

Tetracycline, which has been shown to be effective in cases of canine ehrlichiosis, is also effective in cases of human ehrlichiosis. Doxycycline (100 mg bid; 2.2 mg/kg body weight bid for children weighing < 45 kg) and tetracycline regimens for 7 to 14 days are curative. Most patients respond rapidly after treatment is begun, and fever subsides within 24 to 48 hours. Tooth staining is no longer considered a concern for children and should not be a reason to withhold therapy. Rifampin, as an alternative, has been shown to be effective in children with human ehrlichiosis. Data supporting the use of chloramphenicol are still inconclusive. The same ticks that transmit HGA (*Ixodes spp.*) also are responsible for Lyme disease and babesiosis. Each disease entity requires a full diagnostic evaluation because amoxicillin treats Lyme disease but not HGA or babesiosis, and doxycycline alone does not treat babesiosis. Failure of fever to resolve beyond 6 or 7 days of treatment of a suspected tickborne disease should heighten suspicion for another disease organism.

**BABESIOSIS**

Babesiosis is a tickborne, malaria-like, acute febrile illness caused by intraerythrocytic protozoal parasites of the genus *Babesia*. Babesiosis has long been recognized as an important veterinary disease and probably was known in ancient times; it has been proposed that the fifth plague described in the book of Exodus was actually babesiosis.

The first human cases of babesiosis were reported in Montana in 1904. Investigators seeking the cause of RMSF examined blood smears from local inhabitants and described parasitic forms now known to be characteristic of *Babesia*. Since the late 1950s, several widely scattered cases (mostly in Europe) of human babesiosis have been reported in splenectomized persons. *Babesia divergens*,
a species primarily infecting cattle, is the most common agent reported in Europe, but other species have been implicated as well, including *Babesia bovis*, *Babesia equi*, and a single case of *Babesia caucasica* infection. Two strains, WA1, related to a canine pathogen, *Babesia gibsoni*, and MO1, related to *B. divergens*, also have been found to cause disease in humans. In all these reported cases, the course was fulminant and the disease usually fatal.

Until to the late 1960s, more than 350 cases had been documented in the United States. Almost all these cases were caused by *Babesia microti*, a rodent parasite, and occurred in the coastal regions of southern New England, where *B. microti* is endemic. New Jersey and the eastern part of Long Island were found to be endemic with babesiosis as well. In 2011, babesiosis became a nationally reportable condition. Of the 27 states that elected to participate, 1762 cases were reported from 22 of them; 95% of cases came from seven states—Connecticut, Massachusetts, Minnesota, New Jersey, New York, Rhode Island, and Wisconsin, and 85% of these patients presented with symptoms in June through August, coinciding with the nymphal feeding period and time of maximal human exposure in endemic areas. Recently, case numbers have increased significantly in the lower Hudson Valley in New York and in eastern Pennsylvania.

These cases differ from the European cases in that most (~80%) occurred in persons with intact spleens. Significant morbidity has been low in the United States, despite lack of specific therapy. Asplenic persons, older adults, and otherwise immunosuppressed patients usually have more severe disease.

**Pathophysiology**

*B. microti* is associated with deer and mice rather than with cattle. The ecology of *B. microti* is similar to that of *B. burgdorferi*, the causative agent of Lyme disease, with the same major vector, *I. scapularis*, and the same mammalian reservoirs—white-footed mice, which host the larval and nymphal stages of the tick, and white-tailed deer, which host the adult ticks.

Human babesiosis results from accidental human intrusion on the natural cycle of infection. The nymphal form of the *Ixodes* tick most commonly transmits the disease to humans, although babesiosis also can be transmitted by the adult tick. *I. scapularis* nymphs measure only 1 to 2 mm long and thus are easily overlooked by the patient (see Fig. 126.4). In more than 50% of all cases of babesiosis, patients cannot recall tick exposure. Babesiosis acquired through blood transfusion has been well documented.

**Clinical Features**

Babesiosis has an incubation period of 1 to 4 weeks after tick exposure. A nonspecific influenza-like illness, with fever, chills, headache, fatigue, and anorexia, is characteristic. Less common manifestations are nausea, diaphoresis, depression, photophobia, myalgias, arthralgias, dark urine, emotional lability, and hyperesthesia. Unlike in Lyme disease, rash is not a feature of this illness; however, erythema figuratum, a widespread exanthem with well-established annular lesions, has been associated with septic babesiosis. The physical examination usually reveals normal findings, except for fever, which typically is present, and splenomegaly, which occurs in some patients. Meningeal signs are absent. More severe disease occurs in splenectomized patients; hypotension, severe hemolytic anemia, hemoglobinuria, jaundice, renal insufficiency, ARDS, and disseminated intravascular coagulation can be seen in these cases. Some patients with babesiosis are only mildly ill, and asymptomatic infection also may occur, as demonstrated by serologic surveys in endemic areas. The diagnosis of babesiosis should be considered in any febrile patient from an endemic area during the tick season and should be part of the differential diagnosis for posttransfusion infections.

**Diagnostic Testing**

The diagnosis may be established through microscopy, antibody detection through IFA staining, or PCR assay. Microscopic examination is done with thick and thin Giemsa-stained blood smears. Characteristic intraerythrocytic forms (piriform, ring, tetrad) may be present. Babesiosis has been known to be misdiagnosed as malaria. Malaria may be excluded by the absence of intracellular pigment granules, schizonts, and gametocytes. The presence of parasites in budding tetrad formation, resembling a Maltese cross, is more suggestive of babesiosis. Contrary to what is commonly taught, this finding is uncommon. Because parasitemia may vary, serial smears over the course of several days may be necessary in suspected cases. An immunohistochemical assay has been developed that further allows easier microscopic differentiation between babesiosis and malarial organisms.

The diagnosis can be confirmed by serologic studies. IFA antibody to *B. microti* is available through the CDC, and titers usually rise to 1:1024 or greater within the first few weeks of illness. IgM–indirect IFA is sensitive and specific in acute babesiosis. Serologic tests for Lyme disease, which shares a common tick vector with babesiosis, also should be performed; concurrent Lyme disease has been reported in up to 50% of cases of babesiosis. ELISA and IFA sensitivities rise significantly after 5 days of illness, whereas PCR is more useful in the earlier days of sampling.

Parasitemia observed at 1 to 4 weeks after inoculation of blood from infected patients into gerbils or hamsters supports the diagnosis. Other nonspecific laboratory findings include mild to moderate hemolytic anemia, which is present in most patients, and resultant mild elevations in bilirubin and serum lactate dehydrogenase levels.

**Management**

Patients who have not undergone splenectomy generally recover without specific therapy, although prolonged malaise and fatigue are common. In patients with severe disease and those who have had splenectomies, the combination of clindamycin (1.2 g bid IV or 600 mg tid orally) plus quinine (650 mg tid orally) has been shown to be effective and is the treatment of choice. An alternative regimen that may be better tolerated, especially by children and infants, consists of atovaquone (750 mg bid orally) plus azithromycin (500–1000 mg once followed by 250 mg once daily orally); up to 25% of patients may have an adverse effect from quinine. Pediatric doses need to be adjusted accordingly. Therapy should be continued for a minimum of 7 to 10 days. Development of resistance during treatment with azithromycin–atovaquone in immunocompromised patients has been described.

Other antimalarial drugs, such as chloroquine and quinacrine, are not effective. Fulminantly ill patients with marked degrees of parasitemia and hemolysis have benefited from exchange transfusion. Effective live vaccines have been developed for bovine babesiosis but have not been developed yet for human disease.

**COLORADO TICK FEVER**

Endemic to the Rocky Mountain area, Colorado tick fever is an acute, tickborne viral infection characterized by headache, back pain, biphasic febrile course, and leukopenia. The causative agent of Colorado tick fever is a small RNA virus of the genus *Coltivirus*, family Reoviridae. It is one of more than 500 viruses in the heterogeneous group of arthropod-borne viruses (arboviruses). Colorado tick fever has a sharply defined endemic zone encompassing mountainous and highland areas, from an altitude of approximately 4000 to more than 10,000 feet, in the Canadian provinces of British Columbia and Alberta and in at
least 11 western states (California, Colorado, Idaho, Montana, Nevada, New Mexico, Oregon, South Dakota, Utah, Washington, and Wyoming). The largest number of cases has been reported in Colorado. The distribution of the virus coincides with that of its principal tick vector, *D. andersoni*, the Rocky Mountain wood tick. Although RMSF is transmitted by the same vector, that disease is far less common in Colorado. The cases of RMSF are outnumbered at least 20-fold by cases of Colorado tick fever.

**Pathophysiology**

The Colorado tick fever virus has been isolated from at least eight species of ticks, but *D. andersoni* is the only proven vector for humans. The tick is a significant reservoir for the virus because transstadial transmission (from larva to nymph to adult) of virus occurs, and the tick remains infected and infectious for life, up to 3 years. The primary vertebrate host species for Colorado tick fever virus maintenance are the chipmunk, *Tamias minimus*, and golden-mantled ground squirrel, *Spermophilus lateralis*; many other vertebrate hosts have been identified as well, including a species of porcupine in Colorado in Rocky Mountain National Park. Larval and nymphal stages of *D. andersoni* ticks are responsible for the transmission of Colorado tick fever virus among rodents, and overwintering of the virus is accomplished by nymphal and adult *D. andersoni*. Only adult ticks transmit Colorado tick fever virus to humans.

The CDC indicates that there were 83 cases reported between 2002 and 2012 in the United States. The actual incidence undoubtedly is much higher because many cases are diagnosed as nonspecific viral illness, and other cases may be mild or entirely subclinical. Human susceptibility to Colorado tick fever is universal, but it occurs most commonly in young men, reflecting greater occupational and recreational tick exposure.

**Clinical Features**

After an incubation period of approximately 3 to 5 days (range, 0–14 days), a moderate to severe influenza-like illness occurs abruptly, with signs and symptoms similar to those in early-stage RMSF. Fever, chills, headache, retrobulbar pain, myalgia, lethargy, anorexia, and nausea are common; vomiting and abdominal pain are reported occasionally. Early physical findings are nonspecific. A macular or maculopapular rash has been reported in 5% to 12% of cases. Leukopenia, thrombocytopenia, and fever are reported occasionally. Laboratory findings include a transient leukopenia and, less often, a mild anemia that can occur. These hematologic abnormalities normalize during convalescence, but persistence of the virus in red blood cells causes a prolonged viremia, even when clinical recovery is complete. Transfusion-acquired infection has been reported and is caused by this persistent viremia in asymptomatic blood donors.

The diagnosis of Colorado tick fever can be confirmed by serologic testing (IFA, neutralizing antibody, complement fixation, enzyme immunoassay) of acute and convalescent samples, but serologic study is of little help early because of the slow rise of titers. The most rapid confirmation of Colorado tick fever, with corresponding elimination of concern about possible RMSF, is provided by direct immunofluorescent staining of virus in red blood cells in peripheral blood smears. PCR testing is now available for more rapid diagnosis. ELISA has shown promising sensitivity in detection of the Colorado tick fever virus.

**Management**

The treatment of Colorado tick fever is supportive only. Most patients do not require hospitalization, but if RMSF remains a diagnostic possibility, initial treatment with tetracycline or chloramphenicol and a period of observation are necessary until the diagnosis of RMSF can be ruled out.

**OTHER TICKBORNE VIRUSES**

In addition to the virus responsible for Colorado tick fever, at least 40 viral species have been transmitted to humans by ticks and caused illness, approximately 25 of them in the United States. Tickborne viruses are found predominantly in the RNA virus families. Historically, the most severe cases involved the tickborne encephalitis virus and Crimean-Congo hemorrhagic fever virus, but these have not been reported in the United States. Recently, however, a few tickborne viral illnesses have received notable press in the United States because of their mortality rates—the Heartland virus, a phlebovirus (family Bunyaviridae), the Bourbon virus, a thogotovirus (family Orthomyxoviridae), and a reported severe fever with thrombocytopenia syndrome.

Eight cases of Heartland virus (RNA) disease were found among residents of Tennessee and Missouri as of March 2014. Four patients were hospitalized, and there was one death. All cases presented with leukopenia, thrombocytopenia, and fever. The Bourbon virus, named after the county of its discovery, caused the death of a man in Kansas. Presentations and laboratory results of these new viral syndromes resembled those of other tickborne illnesses and were treated with antibiotics empirically and unsuccessfully. Various neurologic symptoms and encephalitis have been well-described with tickborne viral illnesses. As with most viral illnesses, treatment remains mostly supportive. The emergence and discovery of these newer tickborne diseases suggest that they have been underreported.

**TICK PARALYSIS**

Tick paralysis occurs when an adult female tick attaches to a host and releases a neurotoxin that can produce cerebellar dysfunction or an ascending paralysis. Tick paralysis was recognized as early as the beginning of the 19th century. Hovell, while traveling through Australia, wrote in 1824 of “the small insect called the tick, which buries itself in the flesh, and would in the end destroy either human or beast if not removed in time.”

Tick paralysis has been reported worldwide, but most cases occur in the southeastern and northwestern regions of the United States, western Canada, and Australia. Cases have been reported to occur in clusters; 43 species of ticks have been found to cause tick paralysis in humans, other mammals, or birds. Most cases in
North America and Canada are caused by *D. andersoni* (Rocky Mountain wood tick) and *D. variabilis* (American dog tick). Species responsible for paralysis cases that also are associated with other tickborne diseases include *A. americanum* (Lone Star tick), *I. scapularis* (black-legged tick), and *I. pacificus* (western black-legged tick); in Australia, *Ixodes holocyclus* is primarily associated with this disorder. Family Argasidae ticks (soft ticks) also have been implicated. Tick paralysis usually occurs in the spring and summer months and most reported cases are in children, primarily girls, probably because ticks are more easily concealed in longer hair. Among adults, however, more men than women acquire the disease.

**Pathophysiology**

Tick paralysis is thought to be caused by a toxin secreted from the salivary glands of the tick during a blood meal. The toxin, ixobotoxin, affects sodium flux across axonal membranes without affecting the neuromuscular junction itself. The mechanism of action of the toxin is poorly understood, but it appears to produce a conduction block in the peripheral branches of motor fibers, resulting in a failure of release of acetylcholine at the neuromuscular junction. Electrophysiologic studies have confirmed a rapid reversal of significant impairment of motor nerve terminal function after tick removal, indicating that the disturbance is not a result of a neuromuscular junction defect. Possible central sites of action of the toxin have been postulated to explain cases in which the clinical picture is dominated by cerebellar dysfunction.

**Clinical Features**

The onset of symptoms usually occurs 4 to 7 days after the tick attaches. Initial manifestations include restlessness and irritability, followed by ascending flaccid paralysis, acute ataxia, or both. Deep tendon reflexes are almost invariably lost. These signs and symptoms can progress rapidly during a few days to bulbar involvement, respiratory paralysis, and ultimately death if the tick is not detected and removed.

The ascending nature of tick paralysis has been noted in most descriptions; however, ataxia and associated cerebellar abnormalities in the absence of muscle weakness may be seen. Thus, tick paralysis may sometimes be manifested as so-called tick ataxia. Isolated facial paralysis has been reported in patients with ticks embedded behind the ear. Fever, other systemic symptoms, and sensory deficits are unusual. Concomitant infection with Colorado tick fever has been reported.

**Differential Diagnosis**

Tick paralysis should be considered in the differential diagnosis for any patient thought to have Guillain-Barré syndrome, Eaton-Lambert syndrome, myasthenia gravis, poliomyelitis, botulism, diphtheritic polyneuropathy, or any disease with an acute onset of ascending flaccid paralysis or acute ataxia. Ocular findings, such as decreased convergence, unresponsive dilated pupils, and nystagmus (horizontal and vertical), seen early in tick paralysis can help distinguish this disease from Guillain-Barré syndrome.

**Diagnostic Testing**

No diagnostic tests to confirm tick paralysis are available other than the combination of the clinical scenario, presence of a tick, and improvement after its removal. The Tensilon test yields a negative result in patients with this condition, and CSF is normal.

---

**Recommended Method for Tick Removal**

1. Remove an embedded tick by grasping it with blunt forceps or tweezers as close to the point of attachment as possible.
2. Do not use bare fingers to remove ticks from animals or humans; when tweezers are unavailable, fingers should be shielded with a tissue, paper towel, or rubber glove.
3. Apply gentle, steady, upward traction with the forceps; do not twist or jerk the tick. Avoid squeezing or crushing the tick.
4. Do not handle the tick with bare hands. After removal of the tick, thoroughly disinfect the bite site and wash hands with soap and water.
5. Dispose of ticks by placing them in a container of alcohol or flushing them down the toilet.

**Management**

Treatment in the United States consists simply of removing the tick; improvement generally is seen within a few hours and complete recovery within 48 hours. Supportive care, including mechanical ventilation, may be necessary. The mortality rate is approximately 10%; nearly all patients who die are children. The recommended procedure for the removal of any tick, including ticks causing tick paralysis, is summarized in Box 126.2. Traditional methods, such as burning, forceful removal, and application of petroleum, viscous lidocaine, or gasoline, are not consistently successful and do not guarantee removal of mouthparts, where the salivary glands and toxin may remain. Retained mouthparts also may cause infection.

Tick paralysis in Australia often is more devastating than in the United States. Symptoms and signs of illness caused by the Australian tick, *I. holocyclus*, do not resolve and often worsen after tick removal. Hyperimmune serum is available in Australia and often is needed because symptoms may worsen up to 48 hours after removal.

**TICK BITE PROPHYLAXIS WITH INSECT REPPELLANTS**

Insect repellents have long been used to prevent mosquito bites. With recent increased public awareness of and concern about tickborne illness, especially Lyme disease, skin and clothing repellents are now also being marketed for tick protection. Three active ingredients in repellents have been shown to be effective against blood-sucking arthropods, including ticks—N,N-diethylm-toluamide (DEET), picaridin in KBR 3023 (known as Bayrepel, Hepidanil, and Autan Repel outside the United States), and p-methane-3,8-diol (PMD) in oil of lemon eucalyptus. The most effective and most studied is DEET. Formulation percentages of DEET vary widely, ranging from 4.75% to 23.8%, giving 1½ to 5 hours of protection, respectively. A long-acting 35% DEET formulation (US Army Extended Duration Topical Insect/Arthropod Repellent [EDTIAR]), available in the United States as Ultrathon (3M), provides protection for 6 to 12 hours. Picaridin is as effective as the 35% DEET formulation. Despite some earlier concerns, toxic and allergic reactions to DEET have been uncommon, and serious adverse effects are rare. Used as directed, concentrations up to 50% appear to be safe, even in young children, although toxic encephalopathy rarely can occur. Use for infants younger than 2 months is not recommended.

Permethrin is actually a contact insecticide rather than a repellent. It can be used as a clothing spray for protection against ticks.
Topical DEET and clothing impregnated with permethrin have been shown to be effective in field trials when each is used alone. Wearing protective clothing treated with permethrin in addition to the use of DEET on exposed skin provides the greatest degree of protection against tick bites.

**KEY CONCEPTS**

- Tickborne illnesses frequently are misdiagnosed as viral or bacterial infections. Early diagnosis can be facilitated by considering these diagnoses in patients who live in or recently have traveled to endemic areas and by routinely asking for a history of recent tick or insect bites in patients who present with febrile illnesses.
- Lyme disease should be suspected in patients who present with signs of a viral illness, monarticular arthritis, meningitis, multiple neurologic abnormalities, or heart block. Diagnosis can be confirmed with serologic testing of acute and convalescent serum samples. Normal physiologic changes from bites should not be confused with erythema migrans.
- Relapsing fever should be suspected in patients who present with recurrent viral-like illness associated with high fever. The diagnosis can be confirmed by the identification of spirochetes on a blood smear obtained during a period of rising temperature.
- Ulceroglandular tularemia should be suspected in patients with slow-healing extremity ulcers associated with large lesions of regional adenopathy (buboes). The diagnosis can be confirmed with serologic testing.
- RMSF should be considered in patients who present with an unexplained febrile illness, even in the absence of a rash or known tick exposure. Delayed diagnosis and late initiation of specific antirickettsial therapy may lead to a fatal outcome. Treatment never should be delayed pending laboratory diagnosis.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
C. Lyme disease accounts for 95% of cases.

126.3. Which of the following clinical pictures is not seen with Lyme disease?
A. Conjunctivitis
B. Hepatitis
C. Meningitis
D. Pharyngitis
E. Pleuritis

Answer: E. Clinical pictures consistent with hepatitis, conjunctivitis, pharyngitis, and meningitis may be seen with Lyme disease.

126.4. A 26-year-old woman presents complaining of muscle and joint aches. She has no past history and takes no medications except over-the-counter analgesics. She describes a pattern of migratory and intermittent muscle aches, which she reports as lasting only hours at any single location and then migrating. The physical examination reveals a mild pharyngitis and conjunctivitis and is otherwise normal. Which of the following statements is true?
A. A history of tick bite should be sought.
B. A rheumatoid factor (RF) level should be determined.
C. An erythrocyte sedimentation rate (ESR) would be confirmatory.
D. Creatine phosphokinase (CPK) levels are likely elevated.
E. Fibromyalgia is likely.

Answer: A. The migratory, short-lived, and intermittent nature of the Lyme-related arthralgias is sometimes the best clue to the diagnosis. The ESR, RF, and CPK values will likely be normal. Both rheumatoid arthritis and fibromyalgia present with progressive and usually symmetrical symptoms. Conjunctivitis, pharyngitis, meningitis, and hepatitis pictures may be part of the Lyme presentation.

126.5. Which of the following statements concerning neurologic manifestations of Lyme disease is true?
A. Bilateral Bell’s palsy is suggestive of Lyme disease.
B. Extremity involvement is symmetric.
C. Reflexes are not lost.
D. Spinal roots and plexi are spared.
E. The most common cranial nerve affected is the third.

Answer: A. The seventh cranial nerve is most commonly affected. Bilateral Bell’s palsy should suggest a possible Lyme diagnosis. Reflexes may be lost. Extremity involvement is usually asymmetric. Plexopathies, thoracic radiculopathies, mononeuritis, and motor radiculitis may all be seen.

126.6. Which of the following statements regarding Lyme carditis is true?
A. Cardiac involvement is uncommon.
B. Electrocardiographic changes are stable and persistent.
C. Onset time from initial illness is 2 or 3 months.
D. The most common manifestation is bundle branch block.
E. Ventricular dysfunction is common and persistent.

Answer: A. Cardiac involvement is uncommon. The most common manifestation is atrioventricular block, which may fluctuate significantly but often resolves as the cardiac inflammation recedes. Onset time from illness is an average of 3 to 5 weeks. Ventricular dysfunction is not common, and the prognosis is good.

126.7. A 33-year-old woman presents with worsening depression, irritability, and hypersomnolence. She was diagnosed with Lyme disease 2 years prior and underwent a full course of antibiotics that was initiated 12 weeks after initial symptom onset. Her psychiatric issues began approximately 6 months ago. Her only medication is citalopram. The physical examination is remarkable for a depressed affect and poor short-term memory by bedside assessment. Which of the following statements is true?
A. A demyelinating syndrome may occur after Lyme disease.
B. Late cranial nerve involvement is not seen.
C. Magnetic resonance imaging (MRI) scanning of the brain will be normal.
D. Paranoia would imply a separate cause from Lyme disease.
E. Peripheral neuropathy is the expected late finding in Lyme disease.

Answer: D. Paranoia would imply a separate cause from Lyme disease.

126.8. A patient returns to the emergency department for follow-up of Lyme titers drawn 2 days earlier during an initial evaluation for ongoing arthralgias, myalgias, and history of a rash. The rash came and went approximately 10 weeks prior. Which of the following statements is true?
A. Early antibiotic therapy will not abolish the antibody response.
B. IgG (immunoglobulin G) antibody may persist for years after successful treatment.
C. IgM (immunoglobulin M) positive and IgG negative suggest Lyme disease.
D. IgM positive and IgG positive suggest Lyme disease.
E. IgM becomes positive within 1 week of infection.

Answer: B. IgG antibody may persist for years after successful treatment.

126.9. A 26-year-old man presents with 2 weeks of headache, fever, and stiff neck during the summer months. Which of the following characteristics would best differentiate Lyme disease from enteroviral infection?
A. Cerebrospinal fluid protein and glucose levels and cell count
B. Enteroviral rash morphology
C. Lyme IgM titer  
D. Presence of arthralgias  
E. Presence of diarrhea

**Answer:** E. Lyme disease most closely resembles reactive arthritis, with an asymmetric, oligoarticular, episodic picture. Eye and genital findings help differentiate, although 10% of Lyme disease patients may have conjunctivitis. Lyme disease and reactive arthritis have huge knee effusions, with a paucity of pain compared with effusion size in Lyme disease. Juvenile rheumatoid arthritis and Lyme disease have negative rheumatoid factor test results. Erythema marginatum occurs with the arthritis of rheumatic fever. Lyme disease patients may meet clinical Jone's criteria for rheumatic fever but lack serologic evidence of streptococcal infection.

126.10. A 29-year-old pregnant female camper presents with concerns about a tick bite and Lyme disease. She was camping in Connecticut 3 days ago and had several tick bites. The last tick was removed yesterday. What should you do?  
A. Administer azithromycin daily for 2 weeks.  
B. Counsel her about signs and symptoms of Lyme disease.  
C. Prescribe amoxicillin.  
D. Prescribe antiinflammatories.  
E. Prescribe outpatient intramuscular ceftriaxone.

**Answer:** C. Antibiotic prophylaxis is indicated in certain circumstances. Lyme disease may be transmitted transplacentally, so prophylaxis is likely indicated. Amoxicillin and macrolides are only first-line agents when doxycycline is contraindicated. Macrolides are third-line agents after doxycycline and amoxicillin.
CHAPTER 127
Tuberculosis

Peter E. Sokolove | Robert W. Derlet

PRINCIPLES

The emergency department (ED) serves as the front line of contact for many persons with untreated tuberculosis (TB) in the United States. Undiagnosed patients, incompletely treated patients, or those with active disease who develop complications may first seek medical care in EDs. For this reason, emergency clinicians must fully understand the complexities of the disease, including the multiple presentations of undiagnosed disease, complications, and initial therapeutic options.

Background

TB is currently the world’s second leading infectious cause of death, and one-third of the world’s population has been infected by TB. Each year, more than 8 million people acquire active TB infection globally, and over 1.5 million die of the disease. In the United States, close to 10,000 new cases of TB are diagnosed each year, and 65% of these cases are in patients who are foreign-born. New challenges of the 21st century include human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS), high rates of immigration from countries with high TB prevalence, increasing occurrence of TB in institutional living settings, increasing rates of poverty, substance abuse, and homelessness, and urban overcrowding. Immigration from endemic countries is major factor. The largest numbers of people with TB originate from Eastern Europe, Africa, and Asia. Homelessness and urban crowding also have contributed to the spread of TB in the United States and globally.

The HIV/AIDS epidemic has affected the continued presence of TB in the United States. The pandemic of HIV-related TB also increased TB cases among non–HIV-infected people owing to the higher numbers of source cases in the community. The rate of TB among patients who are HIV-infected and have a positive TB skin test is approximately 200 to 800 times higher than that estimated for the US population overall.

Pathophysiology

One microorganism, Mycobacterium tuberculosis (MTB), causes human TB in nearly all cases. Humans constitute the sole known reservoir for MTB. Two other pathogenic mycobacteria, Mycobacterium bovis and Mycobacterium africanum have, on rare occasions, been implicated in causing TB. M. bovis is transmitted by drinking milk from diseased cows, which is rare in industrialized nations. M. africanum also is a rare cause of human TB in rural Africa.

MTB is an intracellular, aerobic, nonmotile, non–spore-forming bacillus with a waxy lipid coat. This coating makes MTB resistant to decolorization with acid alcohol after staining—hence, the term acid-fast bacillus (AFB). MTB grows slowly. Its generation time is 15 to 20 hours, compared with less than 1 hour for some common bacteria, and cultures take 4 to 6 weeks to grow on standard solid media. MTB produces neither endotoxins nor exotoxins. Its cell components are immunoreactive; some are immunosuppressive, and others are the agents of granuloma formation, macrophage activation, host toxicity, and modification of the immune response.

Transmission

TB is transmitted with rare exception by the respiratory route, including droplet spread and true aerosolization into microparticles. Patients with active disease expel MTB in liquid droplets during coughing, sneezing, and vocalizing. A single cough or 5 minutes of talking can produce 3000 infectious droplets, and sneezing can produce an even higher number. The droplets rapidly evaporate, and the desiccated bacilli circulate airborne for prolonged periods. These infective particles, or droplet nuclei, measure 1 to 5 µm in diameter, contain one to three tubercle bacilli and, when inhaled, can travel to the distal alveoli. Transmission by nonrespiratory routes, such as direct inoculation, occurs primarily among health care workers.

The susceptible host may become infected when only a few of the droplet nuclei are inhaled. Fomites are not important in the transmission of the disease, and patients’ rooms, eating utensils, and bedding do not require special decontamination procedures. Because the infectious droplet nuclei are airborne, exchange of contaminated air is the most important environmental control. In addition, MTB is susceptible to ultraviolet radiation, so transmission rarely occurs outdoors because of the dilution of infectious particles and exposure to ultraviolet radiation.

The risk for TB transmission increases when source patients have airway and cavitary disease. Infectivity correlates with the number of organisms seen on sputum smear, extent of pulmonary disease, and frequency of coughing. After 2 weeks of chemotherapy, most patients with initially AFB-negative sputum smears can be considered noncontagious. In contrast, patients who initially were smear-positive may still have viable MTB detectable in their post-treatment sputum cultures after 2 weeks of treatment. Patients with extensive disease may still have AFB detectable on their post-treatment sputum smears; these two groups should be considered contagious. There is currently no clear epidemiologic evidence to define contagiousness of patients better after they have started effective therapy. The Centers for Disease Control and Prevention (CDC) has published guidelines requiring the presence of three negative smears on different days as the criteria for removal of a patient from respiratory isolation, but debate about this recommendation is ongoing.

Extrapulmonary TB also may be infectious, but only if it is in the oral cavity or open skin lesion. Transmission of MTB to health care workers caring for patients with skin ulcers and draining tuberculous abscesses has been reported. Irrigation of the abscess may aerosolize the bacilli, forming infectious droplet nuclei.

Pathogenesis

When infectious droplet nuclei are inhaled, the airflow through the bronchial tree tends to deposit them in the midlung zone on the respiratory surface of the alveoli. The deposition launches a
complex series of immunologic events. The pathogenesis of TB is divided into four stages.

Stage 1
The first stage begins when an alveolar macrophage phagocytoses the recently inhaled bacillus. A macrophage from a resistant host can immediately destroy a less virulent bacillus. In these cases, no tuberculous infection develops and the process ends. If a virulent bacillus can overcome a macrophage's microbicidal capability, the infection may progress to the next stage.

Stage 2
When the alveolar macrophage is unable to destroy the inhaled tubercle bacilli, the bacilli replicate until the macrophage lyses. Circulating monocytes are attracted to the site of infection by the released bacilli, cellular debris, and various chemotactic factors. The monocytes differentiate into macrophages and ingest the free bacilli. Initially, these new macrophages are not activated and cannot destroy or inhibit the mycobacteria. The bacilli multiply logarithmically within macrophages and accumulate at the primary focus of infection, called a tubercle. The infected macrophages also may be transported through lymphatics to regional lymph nodes, from which they can reach the bloodstream, with subsequent spread. During this lymphohematogenous dissemination, the pathogens tend to distribute preferentially to lymph nodes, kidney, epiphyses of long bones, vertebral bodies, meningeal areas, and apical posterior areas of the lungs.

Stage 3
The third stage of TB begins 2 to 3 weeks after the initial infection, with development of the immune response that terminates the unimpeded growth of MTB. Cell-mediated immunity occurs through CD4+ helper T cells. These T cells secrete cytokines that attract and activate monocyte-macrophages. Once activated, the macrophages, containing previously ingested mycobacteria and their progeny, kill the bacilli. Mild fever and malaise may develop in association with the immune response at 4 to 6 weeks, but the primary infection is generally insignificant clinically. Eventually, the caseous center inspissates (thickens), and the disease is arrested. This sequence of events, from stage 1 to stage 3, represents the pathogenesis of primary TB in the immunocompetent patient. In most cases, primary TB is subclinical and self-limited. Clinically active TB develops in 8% to 10% of otherwise healthy persons. By contrast, in persons also infected with HIV, progression to acute primary TB occurs at a rate of 37% within 6 months. In the immunocompetent host with strong cell-mediated immunity, the primary lesion is effectively walled off by epithelioid cells.

Stage 4
The final stage usually occurs months to decades after an apparent recovery from the initial infection. TB may progress to stage 4, even in immunocompetent persons. Usually, host factors lead to decreased resistance and reactivation of dormant foci of MTB. Reactivation of dormant foci is responsible for the major clinical manifestations of TB. Exogenous reactivation of patients with well-documented previous TB infection causes clinical disease indistinguishable from that of reactivation TB. Because it may be incorrect to label all late-onset cases as reactivation disease, the preferred term is postprimary TB. Postprimary TB is active or chronic disease in a patient previously infected. In the United States and other developed countries, reactivation is thought to be the primary mechanism of postprimary TB. The primary walled-off tubercle eventually may erode through the bronchial wall and drains its contents, forming a cavity. The liquefied caseous material, teeming with mycobacteria, enters other parts of the lung and outside environment. The spilling of this liquefied material within the lung may produce a caseous bronchopneumonia.

**CLINICAL FEATURES**

**History**

**Present Illness**

Patients with TB may present with a primary infection or, more commonly, reactivation of an old infection. A high index of suspicion should be maintained, and TB should be included in the differential diagnosis of common presenting complaints, such as isolated fever, chronic weakness, weight loss, failure to thrive, and night sweats.

Clinically significant pulmonary TB often is indolent, and signs and symptoms are absent or minimal until the disease advances. The constitutional symptoms of anorexia, weight loss, fatigue, irritability, malaise, weakness, headache, chills and, most commonly, fever can be caused by many other diseases. The fever usually develops in the afternoon; defervescence occurs during sleep, leading to the classic night sweats of TB.

Cough is the most common symptom of pulmonary TB patients presenting to the ED. It may initially be a dry nonproductive cough or, less commonly mucopurulent in nature. Hemoptysis, caused by caseous sloughing or endobronchial erosion, usually is minor but often indicates extensive lung involvement. Many asymptomatic MTB patients present for medical attention because they are alarmed by the hemoptysis. Patients also may complain of pleuritic chest pain, which is caused by parenchymal inflammation adjacent to the pleural surface. Dyspnea with chest pain may indicate a spontaneous pneumothorax. Shortness of breath from parenchymal lung involvement is unusual, however, and, if present, indicates extensive parenchymal disease or tracheobronchial obstruction.

The clinical manifestation of TB in patients presenting to the ED may be especially challenging. In one study, only one-third of ED patients with active pulmonary TB had pulmonary chief complaints. Any vague systemic disorder or fever of unknown cause may represent TB. Atypical presentations are particularly common in infants, older adults, and immunocompromised persons. In infants and young children, the development of large hilar lymph nodes is common. Pulmonary TB should be considered in older adults with chronic cough and failure to thrive. Young adults show the adult pattern of apical pulmonary disease, including cavity formation, suggesting reactivation. Because of reduced immunocompetence, older adults typically have disease manifestations similar to those in young children.

Clinical manifestations of TB in patients coinfected with HIV are even more subtle and nonspecific, especially because these patients are vulnerable to opportunistic infections and neoplasms that can cause the same constitutional symptoms as TB. A synergy between MTB and HIV leads to a greatly increased viral load. Active TB with HIV coinfection has been associated with an increased risk for opportunistic infections and death. Patients with advanced HIV infection commonly have extrapulmonary involvement (seen in 30%) as well as combined pulmonary and extrapulmonary TB (in 32%).

**Risk Factors**

All ED patients who have been coughing, and with risk factors, should be screened for the presence of TB risk factors (Box 127.1). Foreign-born individuals and those living with persons who
recently emigrated from endemic areas of the world are at risk, as are patients with unexplained weight loss or cachexia. One of the most important risk factors is HIV/AIDS with CD4+ levels below 500 cells/µL. Overseas, coinfection with HIV and TB is common and results in increased TB mortality rate. Risks for acquiring TB may also be stratified by age. Because infants and toddlers have poorly developed cell-mediated immunity, they have a much higher incidence of TB than adults. Patients on immunosuppressant drugs such as steroids or antiarthritic immunosuppressant agents are at increased risk. Patients with a history of purified protein derivative (PPD) conversion should be asked about the presence of immunosuppressive medical conditions, which are associated with an increased risk for the development of active postprimary disease through reactivation. Household contacts also have increased risk of TB infection. Health care providers should ask patients with a history of active TB about all antituberculosis medications previously or currently taken and about compliance. Failure to improve after 2 months with an appropriate regimen may signal nonadherence to therapy or the presence of a resistant strain.

Physical Examination
A wasted patient with a cachetic appearance is a hallmark of advanced disease. The patient may show signs of dyspnea or tachypnea. The mental status examination may show subtle abnormalities. Examination of the chest can reveal abnormalities, but is unlikely to establish the extent of disease. Over areas of infiltration, rales may be heard when the patient breathes in after a short cough (posttussive rales), and bronchial breath sounds may be present over areas of lung consolidation. Distant, hollow breath sounds (amphoric breath sounds) may be heard over cavitary lesions. Pleural biopsy can confirm the diagnosis in most patients with severe cavitary disease (but may occur when a tuberculous cavity ruptures and creates a bronchopleural fistula or when a bleb ruptures into the pleural space). Delayed tube thoracostomy and suction result in progressive infection and fibrosis of the pleura that leads to air trapping in the affected lung.

Complications of Pulmonic Tuberculosis

Hemoptysis
Minor hemoptysis is a common complication of acute infection. The destruction of lung parenchyma leads to the rupture of blood vessels. TB also may cause massive hemoptysis. An uncommon complication is the erosion of a tuberculous lesion or cavity into a pulmonary artery, leading to pseudoaneurysm formation (Rasmussen’s aneurysm), with potentially fatal hemoptysis. Alternatively, superinfection of cavities by invasive organisms or tumor development in the scarred lung may cause erosion of bronchial or pulmonary vessels, with resultant major hemorrhage. Affected patients often require emergency surgical resection or selective embolization.

Empyema
An empyema, characterized by extensive, progressive parenchymal disease and cavitation, may develop in patients with TB. Although it is rare, empyema is more common late in the course of the disease in debilitated patients. Rupture of a cavity into the pleural space usually is catastrophic and often is associated with bronchopleural fistula formation. An untreated empyema can result in spontaneous pleurocutaneous fistula formation, presence of a chest wall mass on the radiograph, or rib and vertebral destruction.

Fig. 127.1. Chest radiograph demonstrating cavitary tuberculosis with left-sided pneumothorax. The underlying cause of the pneumothorax was later determined to be a bronchopleural fistula. (Courtesy Dr. John Pearce.)

Box 127.1
Population Groups With Increased Risk for Tuberculosis

- Close contacts of known case
- Persons with HIV infection
- Foreign-born from Asia, Africa, Latin America
- Medically underserved, low-income populations
- Older adults
- Residents of long-term care facilities (eg, nursing homes, correctional facilities)
- Injection drug users
- Groups identified locally (eg, homeless, migrant farm workers)
- Persons who have occupational exposure

HIV, Human immunodeficiency virus.
Airway Tuberculosis

When a cavity drains its highly infectious material into the bronchial tree, the airways not only spread the infection but also develop endobronchial TB. Bronchiectasis commonly complicates endobronchial TB. Bronchial stenosis may result from extensive damage caused by endobronchial TB or from direct extension of infection by tuberculous adenitis or lymphatic dissemination to the airway. Tuberculous bronchostenosis may appear radiographically as persistent segmental or lobar collapse, lobar hyperinflation, and obstructive pneumonia. Tracheal and laryngeal TB are less common than endobronchial TB. Laryngeal disease is the most infectious form; it results from the proximal extension of lower airway disease, pooling of infected secretions in the posterior larynx, or hematogenous dissemination to the anterior larynx. Patients with laryngeal TB also usually have active pulmonary disease.

Superinfection With Fungi

Extensive TB infection often heals with open cavities and areas of bronchiectasis. Superinfection may occur with a wide variety of organisms, including *Aspergillus fumigatus*. The characteristic finding on chest radiographs is the aspergilloma or so-called fungus ball (Fig. 127.2). Aspergillomas are of particular clinical significance because they may cause massive and fatal hemoptysis.

Primary Tuberculous Pericarditis

Primary tuberculous pericarditis usually results from direct extension of infection from the tracheobronchial tree, mediastinal or hilar lymph nodes, sternum, or spine. Pericardial involvement may also result from hematogenous spread secondary to acute miliary TB or from another focus elsewhere in the body. TB is the leading cause of pericarditis among HIV-infected patients in the United States. The predominant symptoms are cough, chest pain, and dyspnea, and the most common signs are cardiomegaly, audible rub, fever, and tachycardia. Complications of pericardial TB include pericardial effusion, constrictive pericarditis, myocarditis, and cardiac tamponade. Cardiac tamponade may result from the accumulation of pericardial fluid or rupture of enlarging lymph nodes into the pericardium. Emergency echocardiography reliably confirms the presence of pericardial fluid.

**DIFFERENTIAL DIAGNOSIS**

Pulmonary Tuberculosis

Bacterial Pneumonia

Segmental or lobar infiltrates on chest radiographs in bacterial pneumonia may easily be confused with those seen in TB, especially primary disease. Compared with TB, however, bacterial pneumonias usually arise with more profound symptoms of systemic toxicity, more acute onset, and elevated white blood cell count. In pulmonary TB, there is no prompt response to antibiotics, as seen in bacterial pneumonia.

Fungal and Nontuberculous Mycobacterial Infections

Histoplasmosis, coccidioidomycosis and blastomycosis, as well as nontuberculous mycobacterial infections—mainly with *Mycobacterium avium* complex and *Mycobacterium kansasii*—may be radiologically indistinguishable from TB. The incidence of these infections is influenced by geographic location. Nontuberculous mycobacterial infection usually involves chronic pulmonary infection in HIV-infected patients. Immunocompetent persons also may become infected with MTB, especially patients with chronic lung disease, such as cystic fibrosis. Other important risk factors include work in the mining industry, warm climate, advancing age, and male gender.

Pneumonias in Patients With HIV Infection

Bacterial pneumonias including upper lobe *Pneumocystis pneumonia* (due to *Pneumocystis jiroveci*) and, rarely, *Nocardia* and *Rhodococcus* infections may mimic TB in patients with HIV infection.

Cavitary Lesions

Lung abscess or cavitating pneumonia caused by *Klebsiella pneumoniae*, *Staphylococcus pyogenes*, or aspiration may appear similar to cavitary TB on chest radiographs. In older patients, especially smokers, bronchogenic carcinoma may mimic TB; this is particularly true of squamous cell carcinoma, which tends to cavitate. Because cancer may cause a focus of TB to spread, the two diseases may be present simultaneously. Other causes of nontuberculous cavitary lesions include *M. avium* complex infection in HIV-negative patients, pulmonary infarction secondary to pulmonary embolus, Wegener’s granulomatosis, and upper lobe bullous disease secondary to emphysema or neurofibromatosis.

Mediastinal Lymphadenopathy

The main considerations in the differential diagnosis for adenopathy include lymphoma and sarcoidosis. In sarcoidosis, lymphadenopathy usually is bilateral, symmetric, and asymptomatic. Lymphadenopathy tends to be unilateral in TB; if it is bilateral, it is asymmetric and associated with parenchymal lung disease. Lymphoma tends to involve bulky mediastinal lymphadenopathy.

Extrapulmonary Tuberculosis

Tuberculous infection involving multiple sites is usually seen in populations of patients less capable of containing MTB infection,
such as infants, older adults, and immunocompromised persons. Extrapulmonary TB may occur in multiple sites, with decreasing relative frequencies in lymphatic, pleural, bone or joint, genito-urinary, meningeal, peritoneal, and other sites. The lymph nodes are the most common site of extrapulmonary TB for otherwise normal and HIV-infected patients. Involvement of the meninges is more common in young children than in other age groups (present in ≈4% of children with TB), and the incidence of TB in the remainder of the extrapulmonary sites increases with age. Less commonly involved locations for extrapulmonary TB include the skin, heart, pericardium, thyroid gland, mastoid cells, sclerae, and adrenal glands.

Lymphadenitis

Tuberculoid lymphadenitis (scrofula) is the most common form of extrapulmonary TB. Scrofula is common in children but most commonly is seen in young women. The patient usually has an enlarging, painless, red, firm mass in the region of one or more lymph nodes, most commonly in the anterior or posterior cervical chain or supraclavicular fossa. Early on, the nodes are discrete rubbery masses that are freely mobile, and the overlying skin is normal. Eventually, the nodes may become matted and harder and the overlying skin inflamed. Fluctuance as well as an abscess or sinus tract may be present if a node erodes through the skin. Systemic signs and symptoms are uncommon, except in HIV-positive patients, in whom lymphadenitis usually is generalized. Pulmonary infection is present in a minority of cases. Considerations in the differential diagnosis include lymphoma, metastatic cancer, fungal disease, cat-scratch disease, sarcoid, toxoplasmosis, reactive adenitis, and bacterial adenitis.

The diagnosis of scrofula usually is made by fine-needle aspiration of an affected lymph node. Although AFB smears are positive in only approximately 20% of cases, granulomatous inflammation may be obvious. Overall, fine-needle aspiration has a sensitivity of 77% and specificity of 93% for TB infection. First-line treatment of scrofula consists of antituberculosis drugs, but surgical excision may be performed when medical therapy has failed or if the diagnosis is unclear. Incision and drainage should not be done because permanent sinuses and prolonged drainage can result.

Bone and Joint Infection

Bone and joint TB remains a disease of older children and young adults in developing countries, and it is increasingly a disease of adults in developed countries. Skeletal TB presumably develops from reactivation of dormant tubercles originally seeded during stage 2 of the primary infection or, in the case of spinal TB, from contiguous spread from paravertebral lymph nodes to the vertebrae. In general, spinal TB (Pott’s disease) accounts for 50% to 70% of the reported cases; the hip or knee is involved in 15% to 20% of cases, and the ankle, elbow, wrists, shoulders, and other bones and joints account for 15% to 20% of cases. Approximately 50% of patients have a previous history or concurrent case of pulmonary TB, and the chest radiograph is normal in appearance in up to 50% of cases.

Patients with Pott’s disease may simply complain of back pain or stiffness. Early changes of spinal TB can be difficult to detect on plain radiographs and include loss of the so-called white stripe of the vertebral endplate subsequent to destruction of subchondral bone. Thus, computed tomography (CT) and magnetic resonance imaging (MRI) should be used when the disease is suspected. Paraspinal cold abscesses develop in 50% or more of cases, with occasional formation of sinus tracts. The abscess can spread the infection up and down the spine, sometimes sparing vertebral bodies along its course, forming the so-called skip lesions. These skip lesions can easily be missed in imaging of the spine for Pott’s disease. The main complication of Pott’s disease is spinal cord compression.

Renal Disease

The kidney is highly vascularized, and hematogenous dissemination to that organ is fairly common. After the typical tuberculous lesions develop within the parenchyma, infection can spread into the calyces, renal pelvis, ureters, and bladder. As a result, tuberculous granulomas, scarring, and obstruction can occur anywhere along the urinary tract. Advanced renal disease and destruction may occur before the diagnosis is made. The urinalysis often reveals pyuria, hematuria, and albuminuria. Sterile pyuria is a classic finding in renal TB but, in many cases with this finding, cultures will be positive for other urinary pathogens. The finding of pyuria in an acidic urine with no organisms isolated should increase clinical suspicion for TB. Complications of renal TB include nephrolithiasis, ureteral obstruction or reflux, recurrent bacterial infections, hypertension, papillary necrosis, renal insufficiency, autonephrectomy and, rarely, development of transitional cell cancer.

Genital Disease

Male genital TB is usually associated with coexistent renal TB. Spread of infection from the kidney may involve the prostate, seminal vesicles, epididymides, and testes. A painless or slightly painful scrotal mass is a typical finding, and the patient may have symptoms of prostatitis, epididymitis, or orchitis. Epididymal or prostatic calcifications may be clues to the diagnosis. TB involvement of the seminal vesicles may lead to infertility.

In women, genital TB disease usually begins with a hematogenous focus in the fallopian tubes. The infection then spreads to the endometrium (in 50% of cases), ovaries (30%), cervix (5%–15%), and vagina (1%). Clinical manifestations may include abdominal or pelvic pain, ascites, infertility, menstrual irregularities and, rarely, vaginal discharge. An ulcerating mass may be present on the cervix. Genital TB may be confused with ovarian or endometrial cancer, Meigs’ syndrome, vulvar or vaginal ulcer, pelvic abscess, cervicitis, or cervical carcinoma. Sexual transmission of TB by persons with active genital TB has been described.

Multisystem Disease

The term acute disseminated tuberculosis refers to active hematogenous spread of MTB to several organs in the body. The term miliary tuberculosis was first used to describe the pathologic lesions, which resemble small millet seeds. This is now used as a clinical term referring to the massive dissemination that leads to systemic illness. Miliary TB occurs when the host is unable to contain a recently acquired or dormant TB infection. In the past, miliary TB occurred mainly in young children after primary infection; today, it is more common in older adults and in persons infected with HIV. Miliary TB often is a subtle disease associated with alcoholism, cirrhosis, neoplasm, pregnancy, collagen vascular disease, or use of corticosteroids or immunosuppressive medications. A presumptive diagnosis can be made rapidly if chest radiographs show a miliary infiltrate (Fig. 127.3). Unfortunately, the classic miliary pattern is absent on radiographs in approximately 50% of cases. Routine laboratory tests generally are not helpful. Hyponatremia from the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) is common and often is associated with meningitis. Panculturing usually has a high yield, and HIV-infected patients may have positive results on blood cultures.

Mortality rates for miliary TB are higher than for the other forms of TB, with one case series reporting a rate of 21%. The
CHAPTER 127

Tuberculosis

Bronchial secretions or direct spread from local sites, such as lymph nodes or fallopian tubes. TB may occur in any gastrointestinal location from the mouth to the anus, but lesions proximal to the terminal ileum are rare. The ileocecal area is the most common site of involvement, producing signs and symptoms of pain, anorexia, diarrhea, obstruction, hemorrhage and, often, a palpable mass. The most common clinical manifestations of gastrointestinal TB are abdominal pain, fever, weight loss, anorexia, nausea, vomiting, and diarrhea. The nonspecificity of these findings, as well as of those on the physical examination, may lead to the misdiagnosis of gastrointestinal TB as an acute abdomen, appendicitis, intestinal obstruction, or cancer. The clinical manifestations of anal TB include fissures, fistulae, and perirectal abscesses.

Tuberculous peritonitis may develop from local spread of MTB infection from a tuberculous lymph node, intestinal focus, or infected fallopian tube. In addition, peritonitis can develop from seeding of the peritoneum in miliary TB or from the reactivation of a latent focus. The patient with tuberculous peritonitis commonly has pain and abdominal swelling associated with fever, anorexia, and weight loss. Diagnosis may be confounded by the similarity of this disease to alcoholic hepatitis and by the fact that high mortality rate often is caused by delay in treatment, which should be initiated immediately on the basis of clinical suspicion and not delayed until confirmation of the diagnosis. A fulminant form of miliary TB may cause the acute respiratory distress syndrome and disseminated intravascular coagulation. In these cases, the addition of corticosteroids (prednisone, 60 mg/day) is indicated.

Central Nervous System Disease

Approximately 6% of all cases of extrapulmonary TB involve the central nervous system (CNS), and CNS involvement remains a grave consequence of tuberculous infection. The peak incidence of CNS TB occurs in newborns to 4-year-old children.

Tuberculous meningitis usually results from the rupture of a subependymal tubercle into the subarachnoid space rather than from direct hematogenous seeding of the CNS. When it is a complication of miliary TB, meningitis usually develops within several weeks of infection. In children, it is an early postprimary TB event, usually appearing within 6 months. Tuberculous cerebral involvement is most marked at the base of the brain, and vasculitis of local arteries and veins may lead to aneurysm formation, thrombosis, and focal hemorrhagic infarction. The vessels to the basal ganglia are usually involved, leading to formation of lacunar infarcts or deficits associated with movement disorders. Involvement of other vessels, such as the middle cerebral artery, may lead to hemiparesis or hemiplegia. Tuberculous meningitis begins with a prodrome of malaise, intermittent headache, and low-grade fever. In 2 to 3 weeks, a protracted headache develops. Vomiting, confusion, meningismus and focal neurologic signs, and coma may follow. Nuchal rigidity may be absent. Diplopia resulting from basilar exudate is present in up to 70% of patients. Hyponatremia may be present because SIADH is common. The cerebrospinal fluid (CSF) white blood cell count usually ranges from 0 to 1500 cells/mL, with a predominance of lymphocytes; however, polymorphonuclear cells may predominate early in the course of the disease. The CSF protein concentration is usually elevated, and the CSF glucose concentration typically is low. The classic triad of neuroradiologic findings in patients with TB meningitis consists of basal meningeal enhancement, hydrocephalus, and cerebral or brainstem infarction. CT or MRI also may reveal rounded lesions typical of evolving parenchymal tuberculomas (Fig. 127.4).

Gastrointestinal Disease

Gastrointestinal TB infection usually is secondary to hematogenous or lymphatic spread but also may result from swallowed bronchial secretions or direct spread from local sites, such as lymph nodes or fallopian tubes. TB may occur in any gastrointestinal location from the mouth to the anus, but lesions proximal to the terminal ileum are rare. The ileocecal area is the most common site of involvement, producing signs and symptoms of pain, anorexia, diarrhea, obstruction, hemorrhage and, often, a palpable mass. The most common clinical manifestations of gastrointestinal TB are abdominal pain, fever, weight loss, anorexia, nausea, vomiting, and diarrhea. The nonspecificity of these findings, as well as of those on the physical examination, may lead to the misdiagnosis of gastrointestinal TB as an acute abdomen, appendicitis, intestinal obstruction, or cancer. The clinical manifestations of anal TB include fissures, fistulae, and perirectal abscesses.

Tuberculous peritonitis may develop from local spread of MTB infection from a tuberculous lymph node, intestinal focus, or infected fallopian tube. In addition, peritonitis can develop from seeding of the peritoneum in miliary TB or from the reactivation of a latent focus. The patient with tuberculous peritonitis commonly has pain and abdominal swelling associated with fever, anorexia, and weight loss. Diagnosis may be confounded by the similarity of this disease to alcoholic hepatitis and by the fact that high mortality rate often is caused by delay in treatment, which should be initiated immediately on the basis of clinical suspicion and not delayed until confirmation of the diagnosis. A fulminant form of miliary TB may cause the acute respiratory distress syndrome and disseminated intravascular coagulation. In these cases, the addition of corticosteroids (prednisone, 60 mg/day) is indicated.
this disease often coexists with other disorders, especially cirrhosis with ascites. Paracentesis is thus essential. The peritoneal fluid is exudative, with a cell count of 500 to 2000 cells/mL. Lymphocytes usually predominate, with rare exceptions early in the process, when polymorphonuclear leukocytes may predominate. AFB smears of the fluid have a low diagnostic yield. Peritoneal biopsy often is necessary to confirm the diagnosis. Treatment is the same as for pulmonary TB, with a 6-month therapeutic regimen.

**DIAGNOSTIC TESTING**

**Laboratory Tests**

Routine laboratory studies generally are not useful in suggesting or establishing the diagnosis of TB in the ED. Normochromic normocytic anemia, elevated erythrocyte sedimentation rate, elevated C-reactive protein (CRP) and serum globulin levels, hyponatremia, and hypercalcemia can occur in active pulmonary TB, but these findings are nonspecific.

**White Cell Stimulation Tests**

The patient’s blood can be tested for sensitivity of its T cells to tuberculin antigens. These tests are called interferon-gamma (IFN-γ) release assays (IGRAs). The QuantiFERON-TB Gold (Quest Diagnostics) and T-Spot (Oxford Immunotec) tests are the most widely available IGRAs. They uses an enzyme-linked immunosorbent assay (ELISA) to measure the amount of IFN-γ released in response to PPD. IFN-γ is a cytokine associated with cell-mediated immunity. Determination of IFN-γ levels also can be used as a diagnostic test for tuberculous pleural effusions, ascites, and pericardial effusions. Clinical studies have reported sensitivity ranges from 90% to 100%. TB infection can be rapidly confirmed in an individual in 2 days, compared with several weeks for a traditional culture. However, a normal study does not completely exclude TB; therefore, cultures should be sent when person thought to have TB has a negative QuantiFERON-TB Gold test result.

**Serology**

Although ELISAs have been developed for several MTB serum antigens, in practice no serodiagnostic approach to the diagnosis of TB currently is in widespread clinical use in the United States. Other countries have discouraged the use of serology. Limitations of the ELISA include inadequate accuracy and reproducibility, inability to distinguish active from latent infection, poor discrimination between MTB and other mycobacteria, and relative cost.

**Diagnostic Imaging**

Plain radiography of the chest is the most useful study for a presumptive diagnosis of pulmonary TB. Increased use of chest CT scans has enhanced the sensitivity of detecting classic TB findings in the lung. Chest radiographic abnormalities are not limited to the classic upper lobe cavitory infiltrates. Primary TB infection and postprimary disease have distinctive radiographic features. A normal appearance on the chest radiograph has a high negative predictive value and is therefore useful in screening ED patients for active pulmonary TB. However, the low false-negative rate among immunocompetent adults increases significantly in HIV-positive patients. Therefore, depending on the clinical circumstances, the absence of specific abnormalities on the chest radiograph does not always exclude active TB, especially in patients with concomitant endobronchial disease and HIV infection.

**Primary Tuberculosis**

Chest radiographic manifestations of primary disease in adults often are not recognized as TB. Primary tuberculous infiltrates can occur in any lobe. In any age group, a pneumatic infiltrate with enlarged hilar or mediastinal nodes should strongly suggest the diagnosis. The infiltrate usually is homogeneous and most commonly involves a single lobe. Thus, primary TB may appear radiographically identical to a bacterial pneumonia, with associated lymphadenopathy, if present, being the only distinguishing feature.

Lymphadenopathy is considered the radiologic hallmark of primary TB in children but is seen less commonly in adults. When present, adenopathy usually is unilateral and associated with parenchymal infiltrate (Fig. 127.5). It may occur bilaterally or, less commonly, may be an isolated finding on chest radiography. Other primary TB chest radiographic findings include a moderate to large pleural effusion, which often is an isolated finding whose prevalence increases with age, and miliary TB characterized by the presence of innumerable, 1- to 3-mm noncalcified nodules dispersed throughout both lungs with mild basilar predominance. When the healed primary focus is visible on the chest radiograph as a calcified scar, it is known as the Ghon focus. Calcified secondary foci of infection are known as Simont’s foci. A Ghon focus associated with calcified hilar nodes is called a Ranke complex. A right-sided predominance in the distribution of the Ghon foci and Ranke complexes is well recognized and probably reflects the higher statistical probability that an airborne infection will affect the right lung. Calcification seen on the chest radiograph indicates healing, but viable bacilli may still exist in a partially calcified lesion.

**Postprimary Tuberculosis**

Postprimary TB typically appears as an upper lung infiltrate or consolidation, with or without cavitation. The lesion may be small or extensive and usually is located in the apical or posterior segment of the upper lobe, but may appear in the superior segment of the lower lobe. Postprimary disease also occurs in the lower lung. In addition, bronchogenic spread can occur, leading to the involvement of multiple lobes (Fig. 127.6). Patients with bilateral upper lobe disease are extremely likely to have TB. The other important recognizable characteristics of postprimary disease are fibrosis and cavitation. These lesions are not purely exudative in that they are associated with a fibrotic pattern of nodules and a
few fine, linear densities. Fibroproductive lesions often are irregular and angular in contour, have strands extending toward the hilum, and demonstrate calcification of one or more nodules and distortion of vascular and mediastinal structures. Severe fibrosis with upper lobe volume loss may eventually lead to retraction of the interlobar fissure and upward displacement of the hilum. The chest radiographic appearance at this stage has been variably referred to as “old scarring,” “no active disease,” or “fibrotic, apparently well-healed TB.” Cavitation should alert one to the potential for high infectivity of the patient and associated complications, such as bronchogenic spread of TB (see Fig. 127.4). The walls of the cavities initially are thick and rough and become thinner and smoother with healing. Chest radiographs of patients with pulmonary TB and HIV infection may be atypical in approximately one-third of cases. Patients with late HIV infection more often demonstrate mediastinal adenopathy or atypical infiltrates and less often have cavitation. Severe immunosuppression has been reported to be associated with a miliary pattern of disease on chest radiographs.

Microbiologic Testing

Sputum Studies

If the clinical or chest radiographic findings suggest the diagnosis of pulmonary TB, mycobacteriologic studies of the patient’s sputum should be ordered. A positive smear supports a presumptive diagnosis, and the number of bacilli seen correlates with infectivity. For patients who are not producing sputum, nebulized induction of sputum is the method of choice for the collection of samples. Induction of sputum with nebulization may increase the risk of TB transmission to health care workers and should be performed only in specially ventilated rooms, preferably not in the ED. When the sputum is not diagnostic in adults, fiberoptic bronchoscopy with bronchial washings, brushings, and bronchoalveolar lavage or transbronchial biopsy may be necessary for the laboratory diagnosis of TB.

Direct Microscopy. Direct microscopic examination of a stained sputum specimen for AFB (ie, an AFB smear) is the most rapid laboratory test widely available to support a presumptive diagnosis of TB, and results usually are available from hospital laboratories within 24 hours. Fluorochrome stains are more sensitive than the traditional Ziehl-Neelsen or Kinyoun methods for the detection of AFB from clinical specimens. Negative findings on an AFB smear, however, do not rule out active pulmonary TB because microscopy is relatively insensitive when performed on samples with small numbers of bacilli. At least 5000 bacilli/mL of sputum must be present for a positive result by microscopy. Overall, AFB smears have a sensitivity of 20% to 80% and a specificity of 90% to 100%. Despite its limitations, microscopy remains an essential diagnostic test because of its ease of performance, low cost, rapid turnaround time, and reasonable diagnostic yield.

Nucleic Acid Amplification Tests

Nucleic acid amplification (NAA) tests take only 24 to 48 hours to yield results. Their overall positive predictive value is about 95%. In some cases, patients with positive TB sputum smears have had negative NAA test results because of inhibitors that may prevent amplification. This has been a rapidly growing field in TB diagnostics, although most EDs do not yet have bedside capabilities. The best role of NAA is to aid emergency clinicians in decision making for patients thought to have active TB. It should not be ordered routinely when the clinical suspicion for TB is low.

Culture

Sputum culture is more sensitive than microscopy for the detection of MTB and is still considered the gold standard diagnostic modality. Liquid culture can detect 10 to 100 bacilli/mL, compared with 5000 to 10,000 bacilli/mL for an AFB smear. When the presence of mycobacteria is established, the specific identification of MTB may be accomplished by subjecting the initial mycobacteria to various isolation techniques. These include the detection of pigmentation on solid culture media, various biochemical tests, high-performance liquid chromatography, and nucleic acid probes. A presumptive diagnosis of TB based on a positive sputum smear usually is confirmed by isolation of MTB by culture. Traditional culture methods using solid media require 3 to 8 weeks for colony formation. The development of liquid culture systems has shortened the detection time to 7 to 14 days.

Tuberculin Skin Test

Although newer serologic diagnostic tests have become widely used in most US hospitals, the tuberculin skin test still continues to be the diagnostic workhorse for the detection of exposure to MTB. The tuberculin test is based on the principle that MTB infection induces sensitivity to certain antigens of the bacillus. These antigens are contained in the tuberculin preparation called PPD. In a person infected with TB, the PPD test result usually turns positive 3 to 8 weeks after the infection, when the immune response is developed. The standard 0.1-mL dose used in skin testing contains 5 tuberculin units (TU). A properly placed needle should leave a blanched distinct wheal 6 to 10 mm in diameter. If the tuberculin dose is incorrectly administered, the test may be repeated immediately at a site several centimeters away. Test results are read 48 to 72 hours after administration of PPD. The largest diameter of palpable induration is measured and recorded in millimeters; erythema by itself is not measured. The precise measurement that denotes a positive test result depends on the patient’s other clinical factors. The current CDC guidelines use 15 mm of induration as a positive test response for people without TB risk factors. Persons with previous TB immunization (see later, “Vaccines for Mycobacterium tuberculosis”) may have a positive PPD result even though they are not infected with TB. However,
a significant reaction to PPD and a long time interval between bacilli Calmette-Guérin (BCG) vaccination and the current skin test make it more likely that the reaction is due to MTB infection. Because the BCG vaccine is imperfect in protecting against MTB infection, and because most vaccinated persons come from areas of high TB prevalence, the CDC has recommended that tuberculin skin test results be interpreted without regard to BCG vaccination status.

**MANAGEMENT**

**Initial Management in the Emergency Department**

**Hemoptysis**

The most emergent presentation of pulmonary TB is massive hemoptysis, defined as loss of at least 600 mL of blood in 24 hours. Exsanguination rarely occurs, and the major morbidity is due to asphyxiation from aspirated blood. Secure the airway with a large-diameter (8-mm) endotracheal tube that can accommodate a fiberoptic bronchoscope. Position the patient with the bleeding lung in a dependent position. Consider selective main bronchus intubation to allow ventilation of the unaffected lung and minimize the spread of blood from the affected lung. Emergent consultation for bronchoscopy, surgical resection, or angiography with selective embolization is required. Immediately place patients thought to have active pulmonary TB in respiratory isolation.

**Fever or Wasting**

Patients with fever and wasting generally should be admitted for an in-hospital evaluation. Patients should be placed in respiratory isolation until the diagnosis of TB has been excluded.

**History of Tuberculosis, Therapy Discontinued**

In patients with vague symptoms and a history of TB, consider reactivation. If necessary, consult the local TB health officer or infectious diseases specialist.

**Antituberculosis Medications**

Three basic therapeutic principles govern the treatment of TB: (1) any treatment regimen must contain multiple drugs to which the MTB organism is susceptible; (2) the therapeutic agents must be taken regularly; and (3) therapy must continue for a sufficient period. In clinical practice, the last principle is the most problematic. The most up-to-date recommendations for the treatment of TB are available from the CDC through online publications or at the CDC website. Medications used to treat MTB generally are divided into first-line and second-line agents. Of these, 10 have been approved by the US Food and Drug Administration (FDA) for the treatment of MTB. The most commonly used first-line agents are isoniazid (INH), rifampin (RIF), pyrazinamide (PZA), and ethambutol (EMB).

**First-Line Agents**

INH demonstrates extremely potent early bactericidal activity and can rapidly decrease the patient’s infectiousness. A small risk of hepatitis (<3%) occurs with long-term treatment. Supplemental pyridoxine is recommended for these patients. RIF also demonstrates strong early bactericidal activity. This agent causes orange discoloration of body fluids, including urine, tears, sweat, and sputum. PZA works against organisms contained in the acid environment of the macrophage. The chief side effect is hepatotoxicity, but this risk is very low at daily doses of 25 mg/kg or less. Polyarthralgias occur commonly (up to 40% of patients) but usually respond to nonsteroidal antiinflammatory drugs or aspirin. EMB is a first-line agent that helps prevent the emergence of RIF resistance during TB treatment. Retrobulbar neuritis can occur, resulting in decreased visual acuity to the point of blindness.

**Second-Line Agents**

Streptomycin must be given parenterally and has a peak of action 1 hour after the intramuscular dose is given. The chief side effects of this potentially teratogenic agent are ototoxicity and nephrotoxicity. Amikacin, kanamycin, and capreomycin also are injectable agents used for drug-resistant TB. As with streptomycin, ototoxicity and neurotoxicity are their major adverse effects. TB strains resistant to streptomycin usually are sensitive to amikacin and kanamycin, and resistance to these last two drugs usually is linked. Cycloserine, ethionamide, and p-aminosalicylic acid (PAS) are oral agents used for the treatment of patients with drug-resistant TB when the strain is presumed or known to be sensitive to these agents. The main adverse effect of cycloserine is psychosis or seizures, which occur in 3% to 16% of patients. Ethionamide is similar to INH in structure and toxicity. Major adverse effects of PAS include gastrointestinal distress (most common), hypothyroidism, and hepatitis. Fluoroquinolones have played a more recent role in the treatment of TB. They are less effective than the first-line agents and are used mainly in the treatment of drug-resistant disease.

**Corticosteroids**

Corticosteroids may prevent constriction in tuberculous pericarditis and decrease the neurologic sequelae in all stages of tuberculous meningitis, especially if they are given early in the disease. The CDC strongly recommends corticosteroids for MTB pericardial or CNS infections. Corticosteroids may provide some benefit to children with bronchial obstruction caused by enlarged lymph nodes. In addition, in patients with pulmonary TB, prednisone, 20 to 60 mg/day may benefit those who continue to experience temperature spiking and lose weight, despite a good bacteriologic response to appropriate antituberculosis therapy.

**Initial Therapy**

Emergency clinicians generally will not initiate treatment prior to consulting public health and infectious diseases specialists. To be successful, treatment must be continuous, ongoing, and monitored closely. A one-time dose of medications is fruitless in a patient who could be lost to follow-up. In some locations, this will require hospital admission with appropriate respiratory isolation.

ED management is appropriate and necessary in certain circumstances, such as TB sepsis or miliary TB, critically ill HIV patients with TB, or life threatening conditions. The CDC website should be reviewed for the most up-to-date treatment guidelines. The goals of therapy are to rapidly kill large numbers of bacilli (bactericidal activity), prevent emergence of drug resistance, and prevent relapse by elimination of dormant or slowly dividing bacilli (sterilizing activity). There are four basic recommended regimens. These are used when the organism is known or presumed to be susceptible to INH, RIF, PZA, and EMB.

Adequate treatment of active TB in patients coinfected with HIV is critical. It has been observed that immune activation from TB enhances systemic and local HIV replication and may accelerate the natural progression of HIV infection. Active TB in
HIV-infected patients has been associated with increased risk for opportunistic infections and death. TB treatment alone leads to a reduction in viral load in these patients. Current recommendations for the initial treatment of MTB in HIV-infected patients are the same as those for patients who are not HIV-infected, with exceptions for complex drug interactions. For example, significant drug interactions between rifamycins used for TB and antiretroviral drugs (protease inhibitors and nonnucleoside reverse transcriptase inhibitors [NNRTIs]) used for HIV infection complicate the treatment of patients with active TB who are coinfected with HIV. For treatment of MTB in patients who are taking protease inhibitors, rifabutin can be used instead of the other rifamycins. When TB treatment is initiated in HIV-positive patients, a paradoxical reaction to medical therapy may develop in some cases. The reaction is manifested with the development of fever, new or enlarging lymph nodes, or worsening of radiographic disease. Severe paradoxical reactions may be managed with a 2-week tapering course of prednisone or methylprednisolone.

**Drug-Resistant Tuberculosis**

Two types of drug-resistant MTB have emerged as a result of spontaneous mutations. Multidrug-resistant TB (MDR-TB) is defined as TB in which the mycobacteria are resistant to two or more first-line antituberculosis agents. Extensively drug-resistant TB (XDR-TB) is TB characterized by resistance to first-line and at least three second-line drugs.

**Multidrug-Resistant Tuberculosis**

The World Health Organization (WHO) has estimated the world wide number of MDR-TB cases at close to one-half million persons. Airborne transmission of MDR-TB is a threat to those who come in contact with infected individuals, including family members, contacts in crowded living situations, and health care personnel. The spread of primary drug resistance is faster when HIV infection is highly prevalent in a population. Because initial TB infection in HIV-infected patients progresses rapidly to active disease, newly infected persons can quickly become source cases for further transmission of the resistant bacilli. In reports on hospital outbreaks of MDR-TB, more than 90% of patients had coinfection with HIV, and case fatality rates were as high as 70% to 90%. However, patients without HIV infection demonstrate excellent clinical responses when treated for MDR-TB.

For the identification of potential cases, health care workers should know the prevalence of drug resistance in their community and the risk factors for drug resistance (Box 127.2). Rapid identification and prompt isolation of these patients, along with other control measures, can reduce the nosocomial transmission of MDR-TB to patients and health care workers. Failure to control drug resistance may lead to widespread dissemination of MDR-TB and to a public health crisis that physicians may confront without control measures, can reduce the nosocomial transmission of TB infection in HIV-infected patients progresses rapidly to active disease.

**Extensively Drug-Resistant Tuberculosis**

XDR-TB was first recognized in patients coinfected with AIDS in South Africa in 2005 and is a major threat in Africa, Asia, and areas of the former Soviet Union. XDR-TB is found in 10% of patients presenting with MDR-TB. The strain has virulence similar to that of MTB, and disease does not progress faster in the absence of antibiotics. As resistance to so many antibiotics has developed, however, this strain has become a major threat, especially in patients with AIDS. Most alarming is a report that as many as 33% of patients with TB coinfected with HIV and MDR-TB had the XDR-TB strain. Mortality rates for this population of patients are high, because few alternative drugs exist. The CDC has reported cases in the United States and has isolated patients as soon as they are identified. EDs could become a major focus for spread of this disease because of overcrowding, initial lack of recognition, and long wait times, exposing innocent patients to XDR-TB. Reports from Africa have shown that XDR-TB also can be transmitted directly to health care workers. Of great concern is the potential for transmission of the disease within the ED by a previously undiagnosed patient with XDR-TB, recently arrived from an endemic country, who presents for treatment of TB-related symptoms or an unrelated condition.

**Vaccines for Mycobacterium tuberculosis**

No universally accepted vaccine program exists for MTB. The BCG vaccine has been used since 1921, but its overall efficacy, duration of protection, and optimal age for administration remain unclear. In the United States, BCG is rarely recommended because of the belief that it may undermine the epidemiologic and diagnostic value of PPD skin testing. BCG use in children is common in some countries, and some hospitals overseas require that staff have a BCG vaccination as a requirement for work. Tuberculin skin tests in patients given previous BCG vaccination usually demonstrate less than 10 mm of induration. Thus, previous BCG vaccination status should be ignored in the interpretation of skin test results. Institutional outbreaks of TB and the emergence of MDR-TB have been sparking reassessment of the BCG issue in the United States. Reports of BCG vaccine efficacy range from 0% to 80%. One meta-analysis has reported the efficacy of BCG vaccine to be approximately 50%. A 60-year study in a Native American population showed a 50% reduction in the development of TB in persons receiving BCG vaccine.

BCG vaccine is currently recommended in the United States only for tuberculin-negative infants and children who cannot take INH and have ongoing exposure to a persistently untreated or inadequately treated patient with active TB, who are continuously exposed to persons with INH- and RIF-resistant TB, or who belong to groups with rates of new MTB infection exceeding 1%

---

**BOX 127.2 Risk Factors for Drug-Resistant *Mycobacterium tuberculosis* Infection**

- Previous unsuccessful antituberculosis treatment
- Failure to respond or adhere to a good treatment regimen
- Human immunodeficiency virus infection
- Injection drug abuse
- Close contact with source cases
- Recent immigration from area with a high prevalence of drug resistance
- Cavitory lung disease
- Homelessness
- Imprisonment
- Drug malabsorption due to gastrectomy or ileal bypass surgery

per year. WHO recommends that all infants in developing countries receive the vaccine.

One decision analysis suggested that BCG vaccination would be more effective than the current annual testing strategy for health care workers. What is not controversial is that the vaccine is strongly contraindicated in persons with HIV infection or another immunosuppressive disease. New vaccines against MTB are being researched, including those using attenuated strains of the MTB complex, recombinant mycobacteria, subunit proteins, and DNA vaccines.

**DISPOSITION**

Acutely ill or older patients may require hospitalization during the first few days of treatment because adverse reactions to TB chemotherapy are common and may occasionally be life-threatening. In addition, severely ill patients may require parenteral drug administration. Patients with TB have a high rate of HIV coinfection, and the comorbid illnesses associated with HIV infection, complex synergy between MTB and HIV, and potentially harmful drug interactions between the antiretroviral agents and rifamycins may favor inpatient treatment for the initial management of these complicated cases.

Hospital admission also is indicated for patients with active or suspected MDR-TB. These patients commonly require observation during initiation of therapy because of the complexity of the treatment regimens, toxicity of the drugs, and need for close monitoring to ensure adherence to treatment and isolation measures. Finally, social issues such as homelessness, presence of infants or immunocompromised persons in the household, substance abuse, and inability for self-care may necessitate hospitalization. The recalcitrant patient constitutes a potential threat to public health, and legal measures for involuntary hospitalization may be required.

Patients who are otherwise well but have suspected TB may be eligible for outpatient treatment in consultation with local county health officials, who agree to assume responsibility for ongoing care of the patient and investigate contacts for possible exposure to TB.

**PREVENTION OF TRANSMISSION IN THE EMERGENCY DEPARTMENT**

EDs often care for patients at increased risk for active pulmonary TB, such as those who are homeless, foreign-born, recently incarcerated, or chronically ill. Accordingly, ED personnel can be at high risk for occupational TB infection. Increased hospital occupancy and ED crowding can lead to extended waiting periods for ED beds and hospital beds. Some EDs may lack an adequate number of TB isolation rooms.

**Early Identification**

For the most effective minimization of infectious exposures among health care workers and other patients, all patients with active pulmonary TB would ideally be placed in respiratory isolation when they initially present at triage, and the CDC has recommended screening for TB at triage. Triage screening protocols can detect patients with more classic presentations of TB, but reported protocols are only moderately sensitive and somewhat cumbersome. Immediate respiratory isolation should be considered for patients with high-risk chief complaints, such as the HIV-positive patient with cough, the person with hemoptysis, or the patient with a history of TB presenting with cough or fever. The best guideline is to initiate respiratory isolation as soon as TB is considered a possible diagnosis. Masks should be placed on these patients before chest radiography is performed.

**Isolation and Environmental Control**

In addition to triage screening, the use of proper isolation facilities and environmental control measures can help prevent TB exposures. Airflow in the ED plays a central role, and inadequate ventilation has been a contributing factor in many nosocomial outbreaks of TB. Ideally, there should be single-pass airflow from waiting rooms to outside the facility. Within the ED, air should flow from clean areas to less clean areas, rather than vice versa. For EDs that frequently see patients with TB, at least one true respiratory isolation room should be available. The CDC recommends that respiratory isolation rooms have at least 12 air changes per hour and have negative pressure (air flows into the room from other ED areas). Other engineering approaches to TB infection control include the use of high-efficiency particulate air (HEPA) filters and upper room ultraviolet light irradiation.

**Personal Respiratory Protection**

ED personnel should be familiar with the appropriate use of respiratory protection against TB. Surgical masks (eg, string tie masks) should be placed on potentially contagious patients to decrease the release of infectious droplets into the air. Air can leak around such masks, however, so they may not adequately prevent health care workers from inhaling infectious droplet nuclei. Thus, surgical masks are used only for source control, not for health care worker protection. More advanced personal respiratory protection devices include N95 particulate respirators. HEPA-filtered masks can also be used for health care worker respiratory protection; these masks were used more extensively before development of the N95 masks.

**Preventive Therapy After Inadvertent Exposure**

Health care workers who are exposed to patients with active pulmonary TB require referral to their primary care physicians or employee health services for follow-up testing and treatment. Tuberculin skin testing or IGRA blood testing usually is performed within days following exposure to establish whether the health care worker was previously infected with MTB. If the baseline test result is negative, a follow-up is performed 3 months later to determine whether conversion has occurred. The CDC has developed guidelines for the treatment of exposed personnel, which can be found on the CDC website.

**KEY CONCEPTS**

- Early recognition of patients with risk for TB should begin at ED triage. Patients thought to have active pulmonary TB should be placed in respiratory isolation as soon as possible.
- TB should be considered in the differential diagnosis of patients who present with fever, cough, and weight loss.
- Risk factors for TB include HIV-infection, immunosuppression, age older than 60 years, foreign-born, homeless, and close contact with known cases.
- Beyond pulmonary manifestations, a variety of extrapulmonary manifestations may occur, including involvement of lymph nodes, pleura, bones, or joints and CNS, genitourinary, and gastrointestinal systems.
- Therapy should be determined based on consultation. The most commonly used agents are INH, Rif, PZA, and EMB. Resistant strains, including MDR-TB and XDR, have been increasing in frequency.

CHAPTER 127: QUESTIONS & ANSWERS

127.1. Which of the following is not a typical vehicle for tuberculosis transmission?
   A. Coughing
   B. Eating utensils
   C. Parenteral transmission
   D. Sneezing
   E. Talking

Answer: B. Bedclothes and eating utensils do not require special decontamination. Parenteral transmission is largely a risk of health care workers (eg, skin ulcers, draining wounds). Talking, coughing, and sneezing all may produce significant droplet spread.

127.2. Which of the following anatomic areas is not a site of preferential organism spread during stage 2 spread of TB?
   A. Kidneys
   B. Long bone epiphyses
   C. Lung bases
   D. Lymph nodes
   E. Meninges

Answer: C. Lung apices are favored rather than the bases. These sites are preferred, possibly because of high oxygen tension.

127.3. Clinically active TB develops in what percentage of immunocompetent purified protein derivative (PPD) converters?
   A. 1%
   B. 5%
   C. 10%
   D. 15%
   E. 20%

Answer: C. TB develops in 10%—3% to 5% in the first 2 years (acute primary) and 5% later in life (reactivation). Patients with HIV infection develop primary TB at a rate of 37% within 6 months and then develop active TB at a rate of 7% to 10%/year.

127.4. Which of the following statements regarding clinical tuberculosis is true?
   A. Exogenous reinfection after past TB gives a clinically distinct picture.
   B. Most clinical TB is from acute primary infection.
   C. Acute infection is usually asymptomatic.
   D. Most ED patients with pulmonary TB have pulmonary complaints.
   E. Large hilar nodes are most common in older adults.

Answer: C. Acute infection is very often asymptomatic or, at most, vague. Exogenous reinfection looks just like primary or reactivation TB. Most clinical TB is from reactivation of dormant foci. Many ED patients with active pulmonary TB have no pulmonary symptoms. Large hilar nodes are most common in infants and children.

127.5. Which of the following is a risk factor for reactivation of tuberculosis in a previously infected person?
   A. All of these
   B. Body weight more than 10% below ideal
   C. Diabetes
   D. Intestinal malabsorption syndrome
   E. Silicosis

Answer: A. Other risk factors are listed in Box 127.2.

127.6. A 26-year-old man with HIV infection presents with chest pain and fever. The evaluation yields a likely diagnosis of pericarditis with effusion. What is the most likely cause?
   A. Cryptococcal infection
   B. Haemophilus influenzae
   C. Lymphoma
   D. Streptococcus pneumoniae
   E. Tuberculosis

Answer: E. Tuberculosis is the leading cause of pericarditis in HIV-infected individuals in the United States. The incidence is 15%.

127.7. Which of the following statements regarding chest radiography findings in pulmonary tuberculosis is true?
   A. Adenopathy may distinguish TB from bacterial pneumonia.
   B. Primary TB typically appears as an upper lobe cavity lesion.
   C. The false-negative rate is 10% in immunocompetent patients.
   D. The false-negative rate is 40% in HIV-infected patients.
   E. The typical TB infiltrate is heterogeneous and multilobed.

Answer: A. Hilar adenopathy may be the only way to suspect TB as opposed to a typical bacterial pneumonia. Primary TB is usually a single-lobe infiltrate with a homogeneous appearance. It is postprimary TB that has a predilection for the upper lobes, with or without cavitation. The false-negative rate for chest radiography in immunocompetent patients is very low, 1%. The rate increases to 7% to 15% in HIV-infected patients and those with endobronchial disease.

127.8. Which of the following statements regarding the radiographic appearance of tuberculosis and infectivity is true?
   A. Chronic fibrotic changes are unlikely to be infective.
   B. Normal radiographs are uncommon with HIV infection.
   C. Only the presence of adenopathy can determine active disease.

REFERENCES

D. Patients with late HIV infection are less likely to have adenopathy.
E. The presence of cavitation implies high infectivity.

**Answer: E.** Cavitation suggests high infectivity. Chronic fibrotic changes cannot differentiate old versus active disease, and many of these patients will have positive sputum. Active disease can only be determined radiographically by serial radiographs. Patients with late HIV infection are more likely to have mediastinal adenopathy and less likely to show cavitations. Normal radiographs are common with HIV infection.

**127.9** What is the most common form of extrapulmonary tuberculosis?
A. Genitourinary
B. Lymphatic
C. Meningeal
D. Peripheral bone or joint
E. Vertebral

**Answer: B.** Lymphatic involvement (eg, scrofula) accounts for 42% of cases.
Bone and Joint Infections

Neha P. Raukar | Brian J. Zink

CHAPTER 128

Background

Historically, bone and joint infections (BJIs) have been described in grim terms. *Aids to Surgery*, written in 1919, noted that “acute infective osteomyelitis … is a very fatal disease.” With septic arthritis, “the patient becomes exhausted from toxaemia or pyemia,” and “ankylosis is the usual most favourable termination.” Advances in diagnostic methods, antibiotic therapy, and surgical techniques have resulted in better patient outcomes; however, new challenges are arising. Antibiotic resistance is evolving, and many patient subsets have reduced host immunity. This combination results in greater complexity in the management of BJIs than has ever been encountered. The emphasis of modern management of BJIs has shifted from prevention of sepsis and death to prompt diagnosis, initiation of treatment, and avoidance of the complications and morbidity associated with chronic bone or joint infections.

The overall occurrence of BJIs appears to have remained constant during the past 4 decades. In hospitalized patients in the United States, the incidence is approximately 1%. Osteomyelitis in children younger than 13 years occurs in 1 in 5000, whereas the incidence of septic arthritis ranges from 5.5 to 12/100,000 individuals. In contrast to the rest of the world, there is no correlation between socioeconomic factors or race and the incidence of BJI in the United States. Both bone and joint infections show a bimodal age distribution, occurring most commonly in people younger than 20 years or older than 50 years. In children, BJIs usually occur in previously healthy individuals, with boys having a slightly increased susceptibility to bone infections. In adults, there are several known risk factors that lead to a higher risk of BJIs.

Orthopedic infections can be classified according to the site of involvement and include osseous (osteomyelitis), articular (septic, pyogenic, or suppurative arthritis), bursal (septic bursitis), subcutaneous (cellulitis or abscess), muscular (infectious myositis or abscess), and tendinous (infectious tendinitis or tenosynovitis) varieties. The terms osteomyelitis literally means inflammation of the marrow of the bone, but it is colloquially used to refer to infection in any part of the bone.

Infectious processes can also be categorized by their onset and are generally designated as acute, subacute, or chronic. An acute infection is one that lasts less than 2 weeks, a subacute infection is one that lasts 2 to 6 weeks, and chronic infections are those that last longer than 6 weeks. Chronic osteomyelitis is also used to define a bone infection that fails to respond to a normal course of antibiotic therapy. A histologic diagnosis of chronic osteomyelitis depends on the presence of necrotic bone.

For the emergency clinician, the most practical way to classify osteomyelitis is as hematogenous, which is more common, or contiguous, with the contiguous type further subdivided based on the presence or absence of vascular insufficiency. This method of classification assists in the interpretation of diagnostic imaging examinations and helps guide management, including antibiotic therapy and surgical intervention.

Anatomy and Physiology

Histologically, bone tissue is classified as compact or spongy. Compact bone forms the shaft of long bones and outer shell of all bone. Spongy bone is found at the ends of long bones and makes up irregular bones. Compact bone is dense and without cavities and consists of longitudinally running Haversian systems, which contain Haversian canals that house vasculature and nerves. Spongy bone, conversely, consists of a bony lattice, the trabeculae, which contains marrow, is more metabolically active, and is less dense than compact bone. The central Haversian canals run parallel to the long axis of the bone and contain the blood supply and reticular connective tissue for the Haversian system. Spongy bone, also called cancellous or medullary bone, has numerous cavities, is located within the medullary cavity, and consists of extensively connected trabeculae.

The gross structure of long bones can be divided into several sections. The diaphysis is the shaft of the bone and contains the compact cortical bone with an overlying periosteum and a medullary canal containing marrow. The metaphysis is the junctional region between the epiphysis and diaphysis. The metaphysis contains abundant trabecular bone, but the cortical bone thins here relative to the diaphysis. Finally, the epiphysis is the area at either end of a long bone and is made up of abundant trabecular bone and a thin shell of cortical bone (Fig. 128.1). In the skeletally mature individual, the epiphysis of most bones is involved in articulation and, instead of being covered by a periosteum, is covered with a thin layer of articulating cartilage, a very thin layer of secretory cells sitting on a loose fibrous stroma that allows frictionless movement of the bones.

Joints are enclosed by a synovial capsule, which consists of a dense fibrous connective tissue that offers structural integrity and is lined with synovial cells that secrete synovial fluid. This forms a sleeve around the articulating bones to which it is attached. In some joints, such as the shoulder, hip, and knee, the synovial membrane extends beyond the epiphysis and attaches to the metaphysis. This anatomic relationship allows bacteria to spread directly from the metaphysis into the joint.

Pathophysiology

Osteomyelitis is an infection of the bone and medullary cavity. Bone is typically resistant to infection unless it is subjected to trauma, disruption of blood flow that deprives the bone of normal host immunity, a large inoculum of blood-borne or external microorganisms, or a foreign body. Hematogenous inoculation usually starts in the metaphysis, given the slow flow of blood in the sinusoidal blood vessels. Acute inflammatory cells migrate to the area, causing edema, vascular congestion, and small vessel thrombosis, which then leads to an increase in the intraosseous pressure compromising blood flow to the bone. Eventually, lack
of blood supply to the medullary canal and periosteum leads to areas of necrotic bone termed sequestra. Bony tissue attempts to compensate for the tensile stresses caused by infection by creating new bone around the areas of necrosis. This new bone deposition is called an involucrum. Given that there is significantly reduced blood supply to this necrotic bone tissue, bacterial infection is often difficult to eradicate with medication alone and, frequently, chronic osteomyelitis requires a combination of surgical debridement and antibiotic therapy.

The evolution of blood flow patterns at the metaphyseal-epiphyseal junction and development of vascular anatomy explain the pathologic features of hematogenous osteomyelitis in the different age groups. In neonates and infants, osteomyelitis readily advances from the metaphysis to the epiphysis and adjacent joint space, leading to septic arthritis. After the first year of life, the infection usually spreads laterally through Volkmann’s canals, breaks through the cortex, and lifts the periosteum to form a subperiosteal abscess. In the adult, after the epiphyseal plate ossifies, anastomoses form between the metaphyseal and epiphyseal blood vessels and infection can once again spread from the metaphysis to the epiphysis and eventually into the synovium and joint space. In addition, the periosteum becomes firmly attached to the underlying bone, limiting subperiosteal abscess formation.

Bacteria congregate in a highly structured community, the biofilm, which plays an important role in the pathogenesis of septic arthritis and osteomyelitis. Within the biofilm, the bacteria are at varying stages of metabolism—some are active, some are slow-growing, and some are dormant. Antibiotics target metabolically active bacteria, such as those in the single cell state (planktonic state), but bacteria in other stages in the biofilm community are more resistant to the effects of antibiotics. Furthermore, Gram staining only identifies planktonic bacteria, which helps explain why Gram stains of aspirated synovial fluid in a suspected septic joint are often negative; therefore, a definitive diagnosis is made only by culture of the synovial fluid aspirate or synovial tissue. Biofilm formation also explains why optimal treatment of a septic joint, especially of prosthetic joints, involves complete surgical débridement.

Hematogenous spread of bacteria causes almost all cases of osteomyelitis in children and in the subset of adults who have vertebral osteomyelitis. In the appendicular skeleton of adults, such as in the foot, hand, skull, maxilla, and mandible, osteomyelitis usually occurs by spread of the pathogens from a contiguous source of infection or direct implantation. Head and neck osteomyelitis is usually caused by sinus disease and odontogenic infection.

Infections from direct implantation of bacteria are caused by deep puncture wounds, such as by an animal bite, and tend to occur in the hands and feet. Although cats account for only 10% of animal bites, significant infection results from 20% to 50% of cat bites versus only 5% of dog bites because of the morphology of feline teeth. Most human bite injuries are related to fistfights and contamination of the metacarpophalangeal joints.
and metacarpals, with infection due to oral flora. Direct implantation of pathogens is also common with open fractures and surgical instrumentation.

Septic arthritis is usually a consequence of hematogenous spread unless there is direct injection of bacteria into the joint. The lack of a basement membrane makes the highly vascular synovium vulnerable to bacterial seeding. Infection occurs first in the synovium, spreads into joint fluid, and finally affects the articular cartilage. Bacterial enzymes and toxins directly damage cartilage. The synovial membrane responds to infection by increasing synovial fluid production, resulting in a large joint effusion, and progresses to ischemic damage to cartilage. Even a small bacterial load in the joint space elicits profound and persistent inflammatory and immune responses. Bacteria can be cleared from the joint, resulting in a sterile-appearing inflammatory response. In response to infection, synovial cells and polymorphonuclear leukocytes release lysosomal enzymes, which irreversibly degrade articular cartilage, creating a painful joint with limited range of motion. In addition, other structures that are enclosed within or adjacent to the synovium, such as bursae, tendons, and bone, may also become damaged in those with septic arthritis.

Causes and Microbiology

Typically, hematogenous osteomyelitis or septic arthritis is caused by a single strain of bacterium, with gram-positive organisms being responsible for most infections. Even though gram-negative organisms account for 43% of cases of community-acquired bacteremia, they result in only about 10% of septic arthritis cases. Trauma predisposes patients to osteomyelitis by environmental pathogens. Patients who are wounded or sustain open fractures in fresh water are susceptible to infections with the gram-negative bacillus Aeromonas hydrophila. People who are bitten by animals, particularly dogs and cats, are at risk for the development of osteomyelitis from Pasteurella multocida. Osteomyelitis caused from human bites is most common in the hand and involves human oral flora, such as Streptococcus anginosus, Fusobacterium nucleatum, and Eikenella spp. In the population of injection drug users, Staphylococcus aureus is the most likely cause of infection, followed by Pseudomonas spp. Pseudomonas aeruginosa is also an important cause of osteomyelitis in puncture wounds, postsurgical wounds, and patients with sickle cell anemia.

Certain underlying disease states predispose a patient to BJIs. These conditions include diabetes mellitus, sickle cell disease, AIDS, alcoholism, injection drug use, chronic corticosteroid use, preexisting joint disease (especially rheumatoid arthritis), and other immunosuppressed states. Postsurgical patients are also susceptible to BJIs, especially those who have implanted prosthetic devices.

Although most BJIs are bacterial, other pathogens include viruses, fungi, and parasites. The microbiology of osteomyelitis and septic arthritis is a function of several host and environmental factors. A patient’s living environment also has some role in determining the incidence of BJIs. For example, people living in crowded conditions where tuberculosis is prevalent are at increased risk for tubercular BJIs, whereas older patients in hospitals and institutions may be more susceptible to infections with gram-negative bacteria. A summary of the organisms that cause osteomyelitis and septic arthritis is presented in Tables 128.1 and 128.2.

The following points deserve special mention:

- In all age groups except neonates, S. aureus is the leading cause of osteomyelitis. In neonates, group B streptococci, Escherichia coli and other gram-negative coliforms, and Staphylococcus epidermidis are the most common pathogens responsible for BJIs.
- Since the introduction of the vaccine, Haemophilus influenzae type b, once a common cause of septic arthritis and osteomyelitis in children younger than 2 years, has essentially disappeared as a pathogen in vaccinated children. Another gram-negative cocacobacillus in the Neisseriaceae family, Kingella kingae has been encountered with increasing frequency. K. kingae can be part of the normal flora of the nasopharynx; like H. influenzae, it can be spread hematogenously to bones and joints. It is a fastidious organism and may be mistaken for Haemophilus or Neisseria spp.
- P. aeruginosa has been reported as a cause of cervical spine osteomyelitis in injection drug users and lumbar spine osteomyelitis in patients with urinary catheters in place for a long time. Pseudomonas colonizes the rubber and plastic inserts in footwear and is therefore seen in soft tissue infections and osteomyelitis of the foot after a puncture wound.
- In older adults and patients with diabetes, gram-negative bacteria account for a higher percentage of cases of bone and joint infections.
- Methicillin-resistant S. aureus (MRSA), methicillin-resistant S. epidermidis, and vancomycin-resistant enterococci (VRE) have emerged as a significant microbiologic problem in the past 2 decades. Multiresistant enterococci pose the greatest potential danger in that no currently available antibiotic regimen is reliably bactericidal against such organisms.
- Certain disease processes are more likely to be due to a polymicrobial infection. This would include diabetic foot osteomyelitis, posttraumatic osteomyelitis, and chronic septic arthritis or osteomyelitis. Furthermore, anaerobic bacteria can complicate polymicrobial infection and may be present more often than is

*Concurrent treatment of *Chlamydia trachomatis* infection should be given to patients with suspected *N. gonorrhoeae* septic arthritis.

Commonly recognized. This is because standard culture techniques may be inadequate to identify them. For example, anaerobic bacteria are reportedly discovered in up to 40% of cases of chronic osteomyelitis.

*Mycobacterium tuberculosis* may affect bones and joints, usually in the axial skeleton. The two most common forms of skeletal infection are vertebral osteomyelitis (Pott’s disease), in which the spine is affected in 50% of cases, and tubercular arthritis, which manifests as a chronic, low-grade inflammatory process that resembles rheumatoid arthritis more than acute septic arthritis.

Patients with human immunodeficiency virus (HIV) infection and AIDS are predisposed to a variety of common and opportunistic pathogens. Although *S. aureus* is still the most likely cause of bone and joint infections in patients with AIDS, fungal and other atypical organisms should be considered. One unusual but particularly characteristic form of osteomyelitis in HIV-positive patients is bacillary angiomatosis. This infection is caused by a ram-negative, rickettsia-like organism that frequently causes osteolytic bone lesions.

### OSTEOMYELITIS

#### Clinical Features

##### History and Physical Examination

The symptoms and signs of osteomyelitis in adults are predictable, although not always present. Patients with osteomyelitis often present with fever, more reliably seen in children, and rigors and may even appear toxic. Systemic complaints of headache, fatigue, malaise, and anorexia are inconsistently reported and are less likely with chronic osteomyelitis. In children with lower extremity osteomyelitis, a sudden limp or inability to bear weight, localized warmth, swelling, and erythema may be reported. A careful review
of the patient’s past medical history should be performed to identify risk factors that may predispose to bone infection.

The physical examination findings of osteomyelitis are fairly specific. The predominant symptom of osteomyelitis is pain over the affected bone. Palpation usually elicits point tenderness over the infected segment. Palpable warmth and soft tissue swelling with erythema may be present, but these findings are variable. In chronic advanced osteomyelitis, the involucrum or sequestrum may be palpated, and sinus tracts that fistulize to the skin may be noted. A so-called sympathetic effusion in the adjacent joint may develop in patients with osteomyelitis, even when the joint is not infected.

Complications

In addition to the development of chronic osteomyelitis, complications of acute osteomyelitis include bacteremia and sepsis. Depending on the location of osteomyelitis, local extension of an invasive suppurative process can lead to septic arthritis, brain abscess, meningitis, spinal cord compression, pneumonia, and empyema. In children, osteomyelitis damages the developing skeleton. If infection involves the epiphysis, permanent growth alterations can occur, resulting in a shorter or deformed extremity on the affected side. Pathologic fractures may occur through sites of osteomyelitis.

Clinical Subsets of Osteomyelitis

Osteomyelitis in Children. Osteomyelitis in children tends to be acute, usually arising from hematogenous seeding of bone, and can often be treated with antibiotics alone. Acute hematogenous osteomyelitis (AHO) is seen in children as young as 3 months and as old as 16 years. Staphylococcus aureus is the most common infecting organism in children of all ages, except neonates (see Tables 128.1 and 128.2). As noted, Haemophilus influenzae is no longer a common cause of AHO.

AHO has a well-established male preponderance (male-female ratio of 2:1 to 3:1) and involves long bones approximately 80% of the time. The site of infection is usually the distal metaphysis because of its increased vascularity, but up to 30% of AHO occurs in other parts of the bone. Children with AHO may have fever, chills, vomiting, dehydration, and malaise, but they usually do not appear toxic. Most children have characteristic pain, limited use of the limb, and are point tender. The diagnostic evaluation for AHO is shown in Fig. 128.2. Blood cultures are positive for the bacterial cause of osteomyelitis in 60% of patients with AHO. A positive blood culture and physical examination consistent with osteomyelitis may be sufficient for a diagnosis of AHO to be made. Figs. 128.3 and 128.4 show typical radiographs of AHO.

Neonatal osteomyelitis is difficult to diagnose because of minimal systemic findings. Osteomyelitis in the neonate is more commonly seen after an abnormal pregnancy or delivery and often accompanies other acute illnesses. Multiple sites of bone involvement are found in approximately 50% of reported cases. Because of the unique vascular anatomy of the neonate, septic arthritis often accompanies osteomyelitis. Osteomyelitis of the flat bones, such as the facial bones, is more common among neonates than any other age group. Group B streptococcus is the leading causative bacterium in neonatal osteomyelitis, but staphylococcal species are still common. As with adults, plain radiographs are a good initial test because abnormalities are identified within days of development of neonatal osteomyelitis; they are usually abnormal by the time the disease is suspected. In the presence of a normal radiograph, the next step for the emergency clinician who suspects neonatal osteomyelitis is magnetic resonance imaging (MRI) in consultation with the orthopedic surgical service.

Two less common forms of osteomyelitis can occur in children, subacute osteomyelitis and chronic recurrent multifocal osteomyelitis (CRMO). Subacute osteomyelitis refers to a form of the disease in which clinical symptoms and signs are slow to appear, and radiographs show small areas of osteomyelitis, usually in the metaphysis of long bones. Cultures of blood and bone are negative more than 50% of the time but usually implicate staphylococcal species when they are positive.

![Fig. 128.2. Algorithm for the use of imaging studies in the emergency department diagnosis of osteomyelitis. CT, Computed tomography; ESR, erythrocyte sedimentation rate; MRI, magnetic resonance imaging; 99mTc-MDP, technetium Tc-99m-labeled methylene diphosphonate.](image)

![Fig. 128.3. Radiograph of chronic osteomyelitis. Diffuse sclerosis of the right hemipelvis includes the ischium and iliac bone, with extension to the right sacroiliac joint. The right acetabulum demonstrates whitting of the femoral head and neck, with marked loss of bone stock. Abutting the right symphysis pubis is increased cortical lucency suggestive of subchondral cystic changes. (Courtesy Dr. Peter Evangelista, Department of Diagnostic Imaging, Rhode Island Hospital, Brown University, Providence, RI.](image)
Like subacute osteomyelitis, CRMO usually affects older children (6–10 years) and adolescents. CRMO is characterized by small foci of infection at various sites in the skeleton. The disease is defined by multiple episodes of indolent infection. Diagnosis is made by radiography because culture of the bone sites is almost always negative. This disease may be associated with certain psoriatic subtypes.

**Vertebral Osteomyelitis.** Vertebral osteomyelitis usually afflicts older adults in a manner analogous to that of AHO in children and appears to be increasing in frequency as the population ages and has more chronic medical diseases. Risk factors in older adults include intravenous (IV) access devices, indwelling lines, and asymptomatic urinary infections, whereas in younger individuals, risk factors include injection drug abuse. The spine is susceptible to bacterial infection because the venous system surrounding vertebral bodies is valveless, permitting two-way flow of blood, and has transverse and longitudinal anastomoses. Infection can readily spread to adjacent vertebral bodies. Vertebral osteomyelitis usually results from hematogenous seeding, direct inoculation at the time of spinal surgery, or contiguous spread from an adjacent infection. A clear source of bacterial hematogenous seeding with positive blood cultures occurs in approximately 40% of cases of vertebral osteomyelitis. *S. aureus* (including MRSA) is
the most common offending agent, followed by aerobic gram-negative rods from urinary or gastrointestinal sources.

Only 10% of patients with vertebral osteomyelitis appear septic or toxic; most patients present with insidious symptoms, leading to delays in diagnosis of up to 4 months. Back pain, seen in roughly 90% of patients, is the most common presenting symptom, and physical examination often reveals tenderness over the spinous process. Neurologic deficits are reported in less than 40% of patients with vertebral osteomyelitis and often coincide with a concomitant epidural abscess. Up to 60% of patients with these abscesses present without fever or leukocytosis. On laboratory testing, the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) level are elevated in 98% and 100% of cases, respectively. Blood culture specimens should be obtained before antibiotic treatment is initiated. Rapid diagnosis and treatment of this medical emergency starts with the initiation of empirical antibiotics, immediate imaging, and early orthopedic involvement.

The imaging strategy for the diagnosis of vertebral osteomyelitis starts with plain radiography, which may show disk space narrowing or destruction of the vertebral endplates or vertebral body. Similar to osteomyelitis in other parts of the body, findings on plain radiographs are not seen until at least the second week of vertebral infection. Bone scintigraphy has been largely replaced by MRI in further imaging of suspected vertebral osteomyelitis. Although computed tomography (CT) is good for defining bone destruction and is often used to assist needle aspiration of the lesion, MRI can identify an epidural abscess and rule out other noninfectious vertebral conditions. MRI has a sensitivity of 90% for vertebral osteomyelitis, with T2-weighted images most valuable in establishing the diagnosis.

Vertebral infections can occur in the lumbar (58%), thoracic (30%), and cervical (11%) spine. Cervical spine osteomyelitis can cause a retropharyngeal abscess; lumbar spine osteomyelitis may be complicated by a psoas muscle abscess. The spinal cord may also suffer ischemic injury if the vertebral infection causes septic thrombosis or compression of local blood vessels. When osteomyelitis affects the thoracic spine, infection can spread to the chest. Paraspinal abscesses, reactive pleural effusions, and empyema have been reported and may mislead the emergency clinician to suspect that the primary problem is not in the spine. The most dreaded complication of vertebral osteomyelitis is the spread of infection into the spinal canal, development of an epidural abscess, and progression of the infection to cause spinal cord injury and permanent paralysis. Fortunately, this occurs in less than 15% of cases of vertebral osteomyelitis. Patients who are at increased risk for paralysis include older adults, those with cervical spine osteomyelitis, and those with serious underlying diseases (eg, rheumatoid arthritis, diabetes mellitus).

The diagnostic procedure of choice for vertebral osteomyelitis is needle biopsy, which can isolate the causative organism. Patients who present with a clinical picture consistent with that of vertebral osteomyelitis require rapid diagnostic confirmation through imaging or by direct needle biopsy performed by a radiologist or surgeon, with or without CT guidance. A delay in the definitive diagnosis puts the patient at risk for the progression of vertebral osteomyelitis to spinal cord compression.

Patients with vertebral osteomyelitis initially require IV antibiotic therapy based on the offending microorganism and its susceptibility. Vertebral osteomyelitis can usually be successfully treated with antibiotics alone; surgery may be required for diagnostic purposes, when there is spinal cord compression, for abscess drainage or debridement, for correction of the progressive deformity, and if the infection recurs after adequate treatment.

Diskitis is a variant of vertebral osteomyelitis. The disk is an avascular structure that depends on nutrient diffusion from adjacent blood vessels in the vertebral body and endplates. The avascular disk creates a rich environment for the bacteria to flourish. Because of the vascular anatomy, adult pyogenic diskitis coexists with vertebral osteomyelitis; in children, however, isolated diskitis is more common. The patient complains of back pain and may refuse to walk. Although bone scintigraphy may show increased uptake in the disk space, MRI better demonstrates the anatomy of diskitis. CT is used to guide aspiration. Cultures of the disk from needle aspiration are reported to be positive for bacteria 30% to 60% of the time, usually y for S. aureus. The disease typically resolves with nonoperative treatment.

Posttraumatic Osteomyelitis. Posttraumatic osteomyelitis is a form of contiguous focus osteomyelitis that results from open fractures, burns, bites, puncture wounds, and surgery and invasive procedures. At least 10% of open fractures later develop osteomyelitis, with the tibia being the bone that is usually affected. The fracture site may be contaminated directly from the environment or iatrogenically secondary to emergency procedures or surgery. The intraoperative implantation of prosthetic devices increases the chance of infection. Severe damage to adjacent soft tissues results in a necrotic nidus of infection that can spread to bone. Polymicrobial infection is more common with this type of osteomyelitis. The imaging of posttraumatic osteomyelitis is complicated by changes induced by surgery and new bone formation in the fracture; therefore, the optimal imaging modalities are MRI and CT.

Osteomyelitis due to direct inoculation associated with joint arthroplasty typically becomes evident about 12 weeks after surgery, but these patients generally do not report relief of their pain after surgery. Patients who have symptoms of infection more than 12 weeks after surgery and who have postoperative improvement of their pain are considered to have a hematogenous source of infection. If either of these presentations is recognized within the first 2 weeks of onset of infectious symptoms, the prosthesis is considered salvageable. After 2 weeks, the chance of eradicating the infection without removal of the prosthesis decreases substantially.

The most common form of postsurgical osteomyelitis is infection of a hip prosthesis, which occurs in 1% to 5% of hip replacement surgeries. Postsurgical osteomyelitis is difficult to diagnose. Fever is often absent, and the patient often presents with a painful joint. S. aureus and S. epidermidis account for 75% of postsurgical and prosthesis-related cases of osteomyelitis. Radiographs are often normal but may show subtle signs of bone resorption and loosening of the prosthetic components. It is difficult to distinguish mechanical from infectious loosening; therefore, joint aspiration, synovial fluid analysis, and bone biopsy performed in a sterile operative setting are undertaken to establish a firm diagnosis. Other imaging techniques such as CT and MRI are used but are difficult to interpret because of scatter from the metallic components and postsurgical changes. Systemic antibiotics cannot penetrate the biofilm, and surgical removal of the prosthesis is usually the only way to cure the infection.

Puncture wounds to the feet have approximately a 2% incidence of development of osteomyelitis. The causative organism is usually S. aureus or beta-hemolytic streptococcus. P. aeruginosa is commonly associated with plantar wounds that occur while a person is wearing rubber-soled shoes. Puncture wounds to other parts of the body are typically nosocomial and are often due to subclavian venipuncture, fetal scalp monitoring, and other invasive procedures.

Diabetic Foot Osteomyelitis. The pathologic changes induced by long-standing diabetes mellitus, such as compromised vascularity, encourage the development of osteomyelitis. The typical patient with diabetic foot osteomyelitis is older than 50 years and has advanced, insulin-dependent diabetes. Over 60% of
patients report polyneuropathy, over 50% report retinopathy, and at least 30% have concurrent cardiovascular disease. The neuropathy leads to repetitive trauma and subsequent foot ulcers. Once the skin has been violated and infected, the altered host defenses of diabetic patients make it easier for infection to occur and spread. Hyperglycemia resulting from the infection allows bacteria to proliferate, impairs leukocyte function, and results in defective chemotaxis, abnormal phagocytosis, decreased bactericidal function, defective antibody synthesis, and decreased complement levels, all of which impair healing and exacerbate osteomyelitis. The infection typically starts in the periosteum of the phalanges, spreads to the cortex, and eventually disrupts medullary bone.

Local findings in diabetic foot infections include swelling, erythema, and sometimes pain. Indolent ulcers and frank cellulitis are seen in more than 50% of cases. Because the process is often chronic, radiographic changes are often notable. Mottled lytic lesions are typical, and air may be present in the soft tissues. The only reliable way for the bacteriologic diagnosis to be made is by surgical culture of the bone; however, wounds that can be probed all the way to the bone have a 90% positive predictive value for osteomyelitis. Bone biopsy for diabetic foot osteomyelitis has a reported sensitivity of 94%. Diabetic foot osteomyelitis is usually polymicrobial. *S. aureus* is the most common pathogen; other organisms include streptococci, Enterobacteriaceae, and anaerobes. Surgical treatment with amputation had been the mainstay of treatment; however, a 10-week antibiotic treatment regimen, including IV administration followed by oral antibiotics, can be successful.

**Osteomyelitis in Sickle Cell Disease.** Patients with sickle cell disease (so-called sicklers) are at increased risk for hematogenous infection, including osteomyelitis. In contrast to AHO in nonsicklers, AHO in children with sickle cell disease usually affects the diaphysis instead of the metaphysis. Also, although *S. aureus* is the most common bacterium in children with sickle cell disease who have osteomyelitis, *Salmonella* spp. are the next most common infecting organism. Reasons for this are not completely understood, although it has been postulated that microinfarcts in the bowel allow *Salmonella* bacteria to seed the bloodstream and lead to hematogenous osteomyelitis.

The differentiation of bone infection from bone infarction in sickle cell patients is a challenge. Fever, toxic appearance, and elevated ESR are more commonly associated with osteomyelitis than with bone infarction. Plain radiographs are not helpful in distinguishing between the two entities, but MRI has been proving useful in differentiating between the two. Another approach is to note the response to conservative therapy—bone infarctions usually improve within 24 to 48 hours, whereas bone infection worsens. Antibiotic treatment of osteomyelitis in the sickle cell patient should include coverage against *Salmonella* with a third-generation cephalosporin.

**Chronic Osteomyelitis.** Most chronic bone infections occur as a complication of posttraumatic infection, surgical procedures, or diabetic foot infections. The inflammatory response to infection triggers bone resorption and cartilage destruction and ultimately leads to bone death (see Fig. 128.3). The necrotic bone acts like a foreign material, providing an inanimate surface to which microorganisms adhere. Clinical signs that the infection has become chronic include the formation of sequestra and presence of draining tracts or fistulas. Chronic infection is almost always polymicrobial and commonly involves anaerobes. Because sinus tract culture is not a reliable method to predict which bacteria are active in the underlying bone infection, direct biopsy of bone is the only option for the accurate diagnosis of most cases of chronic osteomyelitis. Chronically established infections can be remarkably persistent or evolve even in the face of prolonged antibiotic therapy; therefore, treatment commonly involves surgery.

**Differential Diagnosis**

Many processes involving bone may masquerade as osteomyelitis. Bone tumors, such as osteoid osteomas and chondroblastomas, may produce local pain and radiographic changes consistent with osteomyelitis, such as small, round, radiolucent lesions. Ewing’s sarcoma is a tumor of bone marrow in children that can be mistaken for osteomyelitis. Metastatic bone tumors and lymphomas should also be considered in the differential diagnosis of osteomyelitis. Finally, occult fractures, such as buckle fractures in children, present with point tenderness that may be mistaken for osteomyelitis.

**Diagnostic Testing**

**Laboratory Tests**

Initial evaluation in the emergency department (ED) often involves laboratory and radiographic evaluation, but the gold standard to confirm diagnosis is bone biopsy and culture, which also helps guide treatment. Laboratory data are not specific and can only suggest the diagnosis of osteomyelitis. In acute osteomyelitis, the white blood cell (WBC) count can be elevated—typical values range from normal to 15,000/mm³—whereas in chronic osteomyelitis, the WBC count is often normal.

The ESR, a nonspecific measure of inflammation, is more helpful than the WBC count. The ESR is a relatively sensitive marker for infection, and many series have reported elevated ESR and CRP values in patients who have confirmed osteomyelitis. An elevated ESR in the presence of appropriate physical findings should lead one to suspect osteomyelitis, but a normal or slightly elevated ESR does not eliminate the diagnosis. Other inflammatory conditions, such as cellulitis, can cause an elevated ESR, although the degree of elevation of the ESR is often higher with osteomyelitis. In the evaluation of a diabetic foot infection, an ESR greater than 70 mm/hr predicts the presence of an underlying bone infection.

The CRP level, another nonspecific marker of inflammation, increases within the first 24 hours of infection, peaks within approximately 48 hours, and is usually normal within 1 week of therapy. The CRP level may be a better early indicator of disease, but the ESR is most valuable in following response to treatment. Typically, the ESR falls steadily as osteomyelitis resolves and increases should it recur. However, it is common to see elevations in one and not the other parameter, especially when there is development of a concurrent illness or the infection has progressed so that the ESR rises but the CRP rises and falls. In children, an elevated ESR or CRP level is seen in all cases of osteoarticular infection; sensitivity of the use of both the ESR and CRP value is 98%, but a leukocytosis is reportedly seen in only 35% of cases.

**Diagnostic Imaging**

**Conventional Radiography.** Conventional radiography is the initial modality of choice to evaluate osseous changes and, in most cases, will be the only imaging technique used to aid in the diagnosis of osteomyelitis. This is true even though radiographic evidence of osteomyelitis lags behind the clinical picture, and less than one-third of patients have abnormalities on plain radiographs in the first 7 to 10 days after the onset of symptoms.

Conventional radiography is readily available, relatively inexpensive, and useful in the differentiation of infection from trauma and tumors. The characteristic findings of early osteomyelitis on
Radionuclide Bone Scanning. Radionuclide skeletal scintigraphy (bone scanning) is more sensitive than plain radiography for the early diagnosis of osteomyelitis. Bone scanning is especially useful in the presence of prosthetics or other hardware. Radionuclide scans can detect osteomyelitis within 48 to 72 hours after the onset of infection. A radioactive tracer is injected into the bloodstream and given time to bind or accumulate in body tissues, after which a camera is used to determine released radioactivity. An image is created that is evaluated for an increase or decrease in expected uptake of the radionuclide. Given the radiation burden associated with this modality, however, in the past 2 decades, there has been a movement away from skeletal scintigraphy to MRI to diagnose osteomyelitis.

Computed Tomography. CT may be also useful in the diagnosis of osteomyelitis. The bony cortex is particularly well seen on CT, and involucrum and sequestrum formation is easily identified. CT is generally used to detect and define areas of possible infection in bones that are difficult to visualize on plain radiographs, such as the sternum, vertebrae, pelvic bones, and calcaneus. On CT scan, osteomyelitis appears as lucent areas (Fig. 128.5), and gas may be seen in bony abscess cavities. The limitation of CT for the early diagnosis of osteomyelitis is the same as that for plain radiography, in that the disease must be present for more than 1 week for changes to be apparent. The CT scan can guide the surgeon in debridement and resection of infected bone and in choosing a site for diagnostic biopsy.

Magnetic Resonance Imaging. The use of bone scans and CT for the evaluation of osseus anatomy has been decreasing as the availability and image quality of MRI improves while its cost decreases. MRI is useful to help diagnose osteomyelitis but is not helpful in diagnosing septic arthritis. The anatomic resolution of MRI is far superior to that of bone scans and plain radiographs. MRI findings are often evident before an abnormality is detected by other modalities because of the earlier detection of bone marrow involvement and medullary or cortical destruction, periosteal reaction, edema, soft tissue extension, joint effusion, articular damage, and complications of osteomyelitis, such as abscess formation. Whereas the presence of ferromagnetic material is a contraindication to the use of MRI, most materials used in orthopedic surgery, such as titanium and chrome cobalt, do not interfere with this imaging modality. Metal may cause distortion of the signal in the area adjacent to a joint prosthesis, but this does not exclude MRI in this group of patients. Optimal MRI images are obtained with a combination of spin echo T1- and T2-weighted images, short tau inversion recovery (STIR) images, and fat-suppressed, T2-weighted images. Osteomyelitis produces a diminished intensity of the normal marrow signal on T1-weighted images and a normal or increased signal on T2-weighted images (Fig. 128.7). These findings, however, are not specific to osteomyelitis; the differential diagnoses for the MRI findings in acute osteomyelitis are trauma, noninfectious inflammatory and metabolic lesions, and cancer. In cases in which a surgical procedure will be done to obtain a microbiologic diagnosis or is needed to treat osteomyelitis, MRI has obvious advantages over other modalities in detailing the anatomy for the surgeon.

The administration of gadolinium as a contrast agent enhances the interface between normal and abnormal marrow and helps distinguish devitalized bone from normally perfused bone. Gadolinium becomes localized in areas of increased vascularity and blood flow and also helps distinguish soft tissue infections, such as abscesses and cellulitis from osteomyelitis. Whereas contrast agents increase reader confidence in the diagnosis of osteomyelitis,
they do not increase the sensitivity or specificity of the diagnosis of osteomyelitis (Fig. 128.8).

Microbiologic Diagnosis

The most definitive way to diagnose osteomyelitis is to obtain infected bone by needle aspiration or surgical resection. This also helps guide antimicrobial therapy. Culture of draining fistulas or sinus tracts is not an acceptable substitute because these cultured organisms often differ from those in the underlying infected bone. Because osteomyelitis may be polymicrobial or due to unusual microorganisms, especially in immunocompromised patients, cultures for fungal and anaerobic organisms should be included.

Particularly in cases of hematogenous osteomyelitis, cultures of blood, urine, cerebrospinal fluid, when necessary, and pus from other sites of infection can help identify the infecting bacteria. Blood cultures in patients with acute untreated osteomyelitis are positive for the offending bacteria approximately 50% of the time. In chronic osteomyelitis, blood cultures are almost always negative.

The emergency clinician’s diagnostic approach in suspected osteomyelitis has become simpler as radionuclide scintigraphy becomes obsolete. The algorithm in Fig. 128.2 provides a simplified approach to the diagnostic strategy in a patient with suspected osteomyelitis. A few key points should be considered with use of this algorithm:

- Radiographs lag behind the clinical picture.
- In infants and children, the amount of radiation exposure with imaging techniques must be considered.
- If the clinical presentation strongly suggests osteomyelitis, a lengthy diagnostic evaluation should not delay empirical treat-
ment. Culture specimens of blood, urine, and other appropriate sites should be obtained and antibiotic treatment started.

- Imaging studies other than plain radiographs are not required to make the diagnosis of osteomyelitis. Advanced imaging is reserved for surgical planning.

Management

Once the diagnosis of osteomyelitis is considered, the next step is to obtain culture specimens and commence treatment rapidly. The goal of therapy is to contain the infection before bone necrosis occurs because cure rates fall dramatically once this happens. Medical management with antibiotics is usually sufficient for asymptomatic osteomyelitis that is coincidentally discovered during the evaluation of a patient with fever, weight loss, or bacteremia, hematogenous infection caused by sensitive microorganisms or fungi, or hematogenous vertebral osteomyelitis caused by sensitive pathogens.

For all other types of osteomyelitis, including contiguous focus osteomyelitis, diabetic foot infections, posttraumatic osteomyelitis, and implant-related infection, definitive care is frequently surgical. In these cases, a discussion with an infectious disease or orthopedic surgery specialist, depending on the scenario and available services, is appropriate to plan or initiate surgical and medical therapy. The ideal antibiotic for treatment of osteomyelitis should be bactericidal against the offending bacteria, such as beta-hemolytic streptococci and staphylococci (including MRSA), have low toxicity, be chemically stable at the site of infection, and be relatively inexpensive. The low pH of infected bone limits the bactericidal action of some antibiotics, particularly the aminoglycosides. Cephalosporins and penicillins are more stable in this environment. In the ED, empirical broad-spectrum treatment of suspected osteomyelitis should be initiated with an awareness of regional resistance patterns. Although gram-negative organisms are uncommon pathogens, the serious consequences of inadequate treatment justify the inclusion of anti–gram-negative coverage in the initial drug regimen. Once culture results are obtained, the antibiotic regimen can be tailored.

In the case of posttraumatic osteomyelitis, appropriate initial emergency care may help prevent the disease. The proper management of open fractures in the field is to cut away surrounding clothing, pour sterile saline or water over the exposed bone, and cover the wound with moist sterile gauze bandages or a sterile sheet. Only in the case of severe vascular compromise to the distal limb should an open fracture site be manipulated or realigned because of the danger of introducing bacteria deeper into the wound. Because wound surface cultures in the ED setting are not reliable in predicting future pathogens in bone infections, they need not be done as part of emergency care.

The first treatment priority is adequate coverage of Staphylococcus spp. with a penicillinase-resistant penicillin, such as oxacillin or nafcillin, or first-generation cephalosporin. In patients with a penicillin allergy, vancomycin is an acceptable alternative; however, cure rates with vancomycin are inferior to those with nafcillin or ceftazolin. Vancomycin should be reserved for those patients with an actual type I penicillin allergy. Nonenterococcal streptococci are usually sensitive to antibiotics used to combat staphylococci. Gram-negative bacteria, including Enterobacteriaceae, E. coli, Proteus mirabilis, and Serratia marcescens, are rare causes of osteomyelitis. Third-generation cephalosporins, aminoglycosides, imipenem–cilastatin, and ampicillin are the usual choices for broad gram-negative coverage. Beyond this initial broad-spectrum therapy, treatment for anaerobic bacteria, Pseudomonas, and fungal organisms should be based on clinical suspicion.

The increase in antimicrobial resistance highlights the need for new antibiotics to expand therapeutic options. Second-generation fluoroquinolones, such as ciprofloxacin, and third-generation agents, such as levofloxacin, offer excellent bone and joint penetration and are active against a broad spectrum of gram-positive and gram-negative organisms. Because the blood concentrations of orally and parenterally administered fluoroquinolones are similar, transition to oral treatment protocols for osteomyelitis is pursued after an initial course of parenteral antibiotics. Successful treatment of osteomyelitis correlates best with serum levels of the antibiotic, not the route of administration. Antibiotics should be
dosed to ensure a serum level eight times greater than its minimum inhibitory concentration. Table 128.2 lists common treatment regimens for the variety of bacteria that cause osteomyelitis. The standard recommendation is parenteral antibiotics for 4 to 6 weeks transitioned to an oral course of antibiotics. Treatment of chronic osteomyelitis is a difficult surgical problem. A variety of adjunctive therapies are have been investigated, such as instillation of antibiotic-containing beads into infected bone and hyperbaric oxygen therapy.

Disposition
Patients with osteomyelitis are admitted for IV antibiotic treatment and some will also need operative debridement. After steady-state serum antibiotic levels have been achieved, patients can receive outpatient IV or oral antibiotic therapy.

SEPTIC ARTHRITIS

Principles
Septic arthritis is an orthopedic emergency, and the incidence appears to be increasing. Even with prompt recognition and appropriate care with antibiotics and joint decompression, septic arthritis leads to a loss of function in 25% to 50% of patients. In the United States, the incidence of septic arthritis in native joints ranges from 2 to 10/100,000 and, in the subset of patients with rheumatoid arthritis, the incidence jumps to 30 to 70/100,000.

Septic arthritis usually results from hematogenous migration of bacteria into a joint and is often a monoarticular process. Like osteomyelitis, septic arthritis may also result from the spread from a contiguous focus of infection or by direct inoculation of bacteria. Direct inoculation can result from penetrating trauma or iatrogenically as a consequence of joint aspiration or injection or from infected foreign material, such as a prosthesis. The synovial membrane extends beyond the epiphysis and attaches to the metaphysis in the knee, hip, and shoulder joints, causing the infection to spread from the metaphysis of the femur or humerus into the joint. This explains why septic arthritis may occur concomitantly with osteomyelitis, with infection spreading from bone to joint, and osteomyelitis may also be the result of septic arthritis. The most commonly isolated organism is S. aureus. Polyanarticular involvement is present in less than 10% of pediatric cases and less than 20% of adult cases. In children, concomitant infection is seen most of the time and can be predicted by age older than 3.6 years, CRP level more than 13.8 mg/L, more than 3 days of symptoms, platelet count <314 × 10 cells/µL, and absolute neutrophil count (ANC) >8.6 × 10 cells/µL. Patients with more than three of these findings would benefit from an MRI to identify any adjacent foci.10 A reactive arthritis, which is more common than bacterial arthritis, is a sterile secondary inflammation of a joint, with no identifiable infecting microorganisms in the synovial fluid. Commonly, reactive arthritis occurs after a systemic viral infection but can also develop after a group A streptococcal infection.

Clinical Features

History and Physical Examination
Septic arthritis is usually more acute in onset than osteomyelitis. The predominant symptom of septic arthritis is joint pain, exacerbated with range of motion. The lower extremity is more commonly affected. In infants and children, this includes the knee and hip; in adults, the knee is the site of septic arthritis 50% of the time, followed by the hip (25%) and shoulder (15%). Immunosuppressed patients, especially those receiving corticosteroids, may have septic arthritis with minimal joint pain. It is important in obtaining the patient’s history to identify underlying joint disease, such as osteoarthritis, gout, rheumatoid arthritis, or joint surgery or a past medical history for chronic systemic disease, immunodeficiency, prolonged steroid use, and/or history of injection drug use. In these patients, a careful history may help differentiate chronic joint pain from the acute pain associated with septic arthritis.

On presentation, more than 80% of children and 40% of adults with septic arthritis have a fever; however, constitutional symptoms such as weakness, malaise, anorexia, nausea, and diffuse myalgias are inconsistently reported. Many children who have septic arthritis will not use the involved limb. If the hip is infected, the patient may present with referred pain to the thigh or knee.

On physical examination, tachycardia and hypotension may indicate a generalized septic process. In the neonate or infant, there may be a so-called pseudoparalysis of the affected limb. This can be mistaken for a neurologic problem; however, an isolated true paralysis is far less common than septic arthritis. The inability of a child to bear weight on a lower extremity or to move any joint spontaneously should be considered a sign of septic arthritis and should be adequately ruled out.

In the older child and adult, signs may be more localized. The extremity will usually be held motionless in the position of greatest comfort, which is slight flexion. Palpation of the septic joint will cause exquisite pain, and any maneuver that stretches the synovium, such as flexion and extension, will cause severe pain. The cardinal signs of inflammation—swelling, erythema, and warmth—are commonly found in the infected joint. Joint pain is 80% to 100% sensitive for septic arthritis, and tenderness is 100% sensitive. Periarticular processes such as bursitis, tendinitis, and cellulitis may produce erythema, warmth, and tenderness, but these processes can usually be differentiated from septic arthritis. Palpation of the joint line and maneuvers that stress the synovium and joint are usually not painful in cellulitis. Periarticular processes also do not commonly produce an effusion. In general, the triad of fever (seen in 45 to 60% of cases), pain (seen in 75% of cases), and impaired range of motion suggests septic arthritis. One caveat with the physical examination is that an increasing number of patients have been receiving chronic immunosuppressive drugs; in these patients, the classic history and examination findings may be significantly less dramatic than in their immunocompetent counterparts.

Complications
Septic arthritis leads to two types of serious complications, those involving the joint itself and those that are systemic. The introduction of bacteria into a joint triggers a profound immune response that leads to destruction of the articular cartilage. Bacteria, host synovial cells, chondrocytes, neutrophils, and macrophages all release enzymes and inflammatory chemicals such as collagenase, elastase, hyaluronidase, lipase, and lipoproteinase, which may be destructive to the joint. Damaged articular cartilage has limited repair capacity, and a common result of articular cartilage destruction is arthritis or ankylosis, which results in a stiff immobile joint.

Children are at great risk for epiphyseal damage if the infection extends through subchondral bone. This can result in impaired growth and limb length discrepancy.11 Other tissues adjacent to the joint can be invaded, leading to suppurative destruction of bursae, tendons, ligaments, and/or muscles. Sinus tracts may lead the infection out through the skin. In the hip, the pressure and edema of a septic synovial effusion can occlude the blood supply, resulting in avascular necrosis of the femoral head, especially in neonates.
Systemic complications from septic arthritis are less common but the hematogenous spread of bacteria from an infected joint can produce sepsis, septic shock, and death. Seeding of other sites with bacteria is also a possibility, and this can produce endocarditis, pneumonia, and abscesses.12,14

Clinical Subsets of Septic Arthritis

Bites. The human mouth is a polymicrobial environment comprised of aerobic organisms, such as Staphylococcus, oral gram-negative rods, such as Eikenella corrodens, and anaerobes, such as Fusobacterium, making bone and joint infections caused by human bites difficult to treat. Similarly, animal bites also lead to a polymicrobial infection, with Pasteurella multocida an important additional organism. Antibiotics should be empirically started, but treatment also requires drainage and débridement.

Infants and Children. Septic arthritis is more common in children than in adults, and the incidence of septic arthritis is twice that of osteomyelitis in children. Two-thirds of pediatric cases occur in children younger than 2 years, and boys are affected twice as often as girls. The offending agent in septic arthritis varies with age. In the post–H. influenzae vaccine era, overall, S. aureus (methicillin-sensitive more than methicillin-resistant) is the most common infecting organism in all pediatric and adult age groups, followed by group A streptococci and Streplococcus pneumoniae. In neonates, group B streptococci, S. aureus, and gram-negative enteric bacilli are usual pathogens. Candida albicans should also be considered in neonates and premature infants. K. kingae has been emerging as an important cause of septic arthritis and osteomyelitis in children younger than 2 years. In children between 3 months and 5 years of age, concomitant respiratory infection or otitis media is often present. Prior trauma or skin infection may be more common with staphylococcal septic arthritis.

The Kocher criteria can be used to help identify children with septic arthritis of the hip. However, the sensitivity of the algorithm has been challenged and should be used wisely. The four criteria are fever (temperature ≥ 38.5°C [101°F]), non-weight-bearing on the affected side, ESR greater than 40 mm/hr, and peripheral blood WBC count more than 12,000 cells/mm³ (Table 128.3). Laboratory work, including complete blood count and determination of the ESR and CRP level, are part of the routine evaluation of the limping child but, individually, do not have adequate sensitivity or specificity to rule in or rule out the diagnosis. A synovial fluid analysis should also be done if there is any suspicion for septic arthritis.

Even when cultures of synovial fluid and blood are tested, a causative organism is not discovered in up to 30% of cases of septic arthritis in children. Prior antibiotic treatment in children decreases the yield on synovial fluid cultures from 80% to 38%. In the pediatric population, the hip and knee have equal rates of infection, with each accounting for about one-third of infections. In children, hematogenous osteomyelitis is often associated with septic arthritis of the hip. Concurrent osteomyelitis is present in 20% of infants and in almost 50% of all neonates with septic arthritis.

Gonococcal Septic Arthritis. In the United States, N. gonorrhoeae is the most common cause of septic arthritis in sexually active patients. A person with gonorrhea of the urethra, cervix, rectum, or pharynx has a 1% to 3% chance for the development of disseminated gonococcal infection (DGI). More than 75% of cases of DGI occur in women, possibly because of their increased risk of asymptomatic infection. DGI is common during pregnancy or after menstruation, when the alkaline vaginal environment makes the organisms more resistant to host defenses in the bloodstream and therefore more likely to disseminate.

The classic triad of gonococcal bacteremia is migratory polyarthritis, tenosynovitis, and dermatitis. Asymmetric polyarthralgia, which may be migratory, is the most common presenting complaint, occurring in two-thirds of cases; 25% of patients have monoarthralgia. Polyarthralgia is usually asymmetric and most frequently involves the knee, although the elbow, wrist, metacarpophalangeal, and ankle joints are also affected. The sacroiliac and sternoclavicular joints may be involved, although these sites are far less common. Hemorrhagic pustules on the skin, scattered, painless, nonpruritic, small (0.5- to 0.75-cm) papules distributed below the neck that can involve the palms and the soles, are seen in 41% of cases. These papules can turn into pustules on a broad erythematous base with a necrotic or hemorrhagic center. There are usually fewer than 50 lesions, distinguishing DGI from the rash of meningococcus.

Septic arthritis develops in approximately 40% of patients with DGI. It is usually a monarticular process, although polyarticular septic arthritis has been reported. The patient will present with classic signs of a septic joint, including a joint effusion, warmth, tenderness, decreased range of motion, and marked erythema. There is usually no clear progression of DGI and polyarthralgias to purulent monarticular arthritis, and many patients are afflicted with dermatitis and tenosynovitis without the development of true arthritis. Some strains of N. gonorrhoeae that produce DGI favor the development of tenosynovitis and dermatitis, whereas others favor the development of purulent arthritis.

The diagnosis of gonococcal arthritis is made by synovial fluid culture results, but gonococci are recovered from synovial fluid in less than 50% of cases. In septic arthritis due to gonorrhea, the synovial fluid WBC count is often less than 50,000 cells/mm³. Gram stains of aspirated joint fluid are positive for bacteria only 25% of the time, and cultures of the joint fluid are negative in approximately 50% of cases. This may be due to poor culture techniques or because a suppurative reactive process can occur in the joint in DGI, even when bacteria are no longer present. When gonococcal arthritis is suspected, cultures of the synovial fluid should be plated on prewarmed chocolate agar for the highest yield, and cultures for N. gonorrhoeae should be obtained from mucosal surfaces, because these may be the only places where bacteria are readily recovered. Cultures of the genital tract, pharynx, or rectum will be positive in 80% of cases of gonococcal arthritis. The use of urine nucleic acid amplification tests to detect gonorrhea has been gaining in popularity, given their ease of use. However, in women, vaginal swabs detect more infections than urine sample, whereas in men, detection of gonorrhea from urine samples is equivalent to rates of detection from urethral swabs.

Gonococcal septic arthritis responds rapidly to antibiotic treatment and, unlike other types of bacterial arthritis, rarely causes permanent damage to the joint. Patients with gonococcal septic arthritis require hospital admission, with antibiotic coverage against the likely pathogens until laboratory results are available. With the rise in fluoroquinolone-resistant gonorrhea, the

Kocher Criteria
recommended treatment of gonococcal arthritis is a third-generation cephalosporin, such as ceftriaxone, cefixime, or cefotaxime. Patients are given the first dose via the IV route or intramuscularly in the ED and admitted until culture results are available. If the diagnosis of gonococcal arthritis can be definitely established in the ED, patients with reliable follow-up can be treated with an IV or intramuscular dose of antibiotics and then sent home with an oral regimen, which should be continued for 1 week.

**Lyme Arthritis.** Lyme disease, the most common tick borne disease in the United States, is caused by infection with a spirochete, *Borrelia burgdorferi.* Transmitted by the *Ixodes* tick, it is an important cause of arthritis in endemic areas, and its incidence has been increasing. Lyme disease has been reported in all 50 states, but endemic areas, including Maryland, Massachusetts, Minnesota, New Jersey, New York, Pennsylvania, Wisconsin, Connecticut, Delaware, and Rhode Island, account for 93% of all cases annually. There is a bimodal age distribution in children aged 5 to 9 years and adults aged 55 to 59 years. Children infected by *B. burgdorferi* are more likely than adults to have arthritis as the initial manifestation of the disease. Whereas it is important to determine a history of a tick bite, up to 30% of people do not remember being bitten. There are three phases of the infection—early localized, early disseminated, and late.

Arthritis, which is the most distinguishing feature of late-stage Lyme disease, develops in up to 60% of untreated Lyme patients and is manifested months after disease onset. After infection, spirochetes are disseminated and invade synovial joints, resulting in a profound immune response, similar to that seen in bacterial arthritis. Patients with Lyme arthritis present with migratory polyarthritis that also involves bursae and tendons. This usually evolves into a monarticular process and usually involves single large joints. More than 90% of patients report knee inflammation, but other affected joints include the wrist, elbow, ankle, and hip. The Centers for Disease Control and Prevention has defined Lyme arthritis as “recurrent, brief attacks (weeks or months) of objective joint swelling in one or a few joints, sometimes followed by chronic arthritis in one or a few joints.”

The rash is often overlooked by patients and is generally not present in patients when they present with arthritis. However, fever is noted in up to 50% of all children who have Lyme arthritis. Clinically, the arthritis is similar to other inflammatory processes of the joint and includes warmth, erythema, swelling, and pain on motion of the joints; however, the effusion is usually large and out of proportion to the patient’s complaints. The effusion also generally recurs after aspiration, even when the joint is appropriately treated.

The most widely used test for the diagnosis of Lyme disease is the serum antibody titer, including enzyme-linked immunosorbent assay (ELISA) and Western blot testing, but serum testing does not differentiate between acute and past infections. Synovial fluid analysis is not helpful in distinguishing Lyme arthritis, but it usually reveals an inflammatory process with WBC counts that have been reported to have a very wide range, from 500 to 98,000 cells/µL. Arthrocentesis cannot differentiate between bacterial and Lyme arthritis because serologic analysis is similar. Cultures of synovial fluid in Lyme arthritis are usually nondiagnostic. Testing of synovial fluid with ELISA or Western blot methods for Lyme disease is not recommended because no consensus exists on how to interpret these data. Lyme arthritis can be successfully treated with oral doxycycline, amoxicillin, or cefuroxime for 30 days. If this is unsuccessful, patients can be retreated with the same oral regimen for another 30 days, or the antibiotic can be changed to IV ceftriaxone for 14 to 30 days.

Fortunately, Lyme arthritis has an excellent prognosis. Up to 95% of children remain asymptomatic after a single course of antibiotics; adults may show an increased incidence of persistent joint swelling months to years after the initial infection, even after appropriate antibiotics. A small minority of patients have chronic Lyme disease despite appropriate treatment, with symptoms similar to those of chronic fatigue syndrome.

**Periprosthetic Joint Infections.** Infections occurring after joint replacement are a challenging and dangerous complication of arthroplasty, with rates reported to be 1% to 2% at 2 years postoperatively in native joints and up to 7% in patients undergoing joint revision. The prosthesis and cement are foreign bodies and are ideal sites for bacterial colonization. The most common infectious agents are *S. epidermidis* (40% of cases), *S. aureus,* methicillin-sensitive and methicillin-resistant (20%), and streptococcal species (20%). Risk factors for periprosthetic joint infections have been identified to be rheumatologic disease, preoperative anemia, coagulopathy, diabetes, depression, and low socioeconomic status. The American Academy of Orthopaedic Surgeons clinical practice guideline summary recommends that patients who present to the ED should initially be stratified to high or low probability for a periprosthetic joint infection. As with many diagnostic maneuvers performed in the ED, a pretest probability helps guide the evaluation.

On history and physical examination, the patient will complain of pain that is constant and present at rest, along with impaired function of the joint secondary to loosening of the hardware. Radiographs may also reveal movement of the prosthesis, bone erosion, new subperiosteal bone growth widening, or more than a 2-mm lucency at the bone-cement interface. The investigation starts with laboratory data, including ESR and CRP level. If both test results are negative, a periprosthetic infection is unlikely (negative likelihood ratio, 0.9–0.96); when both test results are positive, a periprosthetic infection must be considered (likelihood ratio, 4.3–12.1). However, many inflammatory processes can result in an elevation of the ESR and CRP level, and these are not specific tests. The use of either test alone is less reliable, and no definitive conclusion can be drawn with just one result. In patients with an elevated ESR or CRP level in whom a prosthetic joint infection is suspected, the next step is to consult the orthopedic service to obtain fluid from the joint under sterile conditions.

If synovial fluid is submitted for analysis, a synovial WBC count more than 1100 cells/mm³ with more than 64% neutrophils is a sensitive and specific marker for periprosthetic joint infection in a patient with an elevated ESR (>50 mm/hr) and CRP level (>10 mg/L). Aspiration may be more difficult in this situation because of scarring and alteration of the joint space. Consultation with the patient’s orthopedic surgeon about the decision to perform joint aspiration in the ED and the selection and timing of antibiotics in suspected periprosthetic joint infection is advisable. Patients who have received antibiotics within 2 weeks will have a very low yield with intraarticular cultures, even if infection is present. Because of the difficulty in isolating infectious organisms from the prosthetic joint, even if done intraoperatively, orthopedists have generally recommended that antibiotics not be started until after culture specimens are obtained.

**Patients With Existing Joint Disease.** Patients with underlying joint disease, especially rheumatoid arthritis and a crystal arthropathy, are more likely to have septic arthritis than their counterparts with normal joints. If septic arthritis is suspected, laboratory and radiographic evaluation is of lower yield and, to reduce mortality, antibiotics are started immediately after synovial fluid is sent for testing. In patients with a crystal arthropathy, neutrophil invasion secondary to septic arthritis also leads to increased precipitation and release of crystals. Therefore, the emergency clinician who discovers crystals on joint fluid aspiration should not abandon the search for an infectious agent.
Atypical Joints. Septic arthritis can be particularly difficult to diagnose and treat if it occurs in fibrocartilaginous joints, such as the sternoclavicular, acromioclavicular, and sacroiliac joints and the symphysis pubis. Septic arthritis of the axial skeleton, especially of the sternoclavicular joint, is commonly seen in injection drug users, with *Pseudomonas* a common infecting agent. In patients who do not have other predisposing factors, the most common bacterial causes are *S. aureus* and *S. epidermidis*. The presentation is usually pain and joint tenderness over the involved joint. Fever and an elevated ESR are commonly reported, although they are not always present because of the suppressed immune status of the patient. When imaging is required, CT and MRI are preferred and are helpful in the diagnosis of septic arthritis in the fibrocartilaginous joints.

Differential Diagnosis

Many disease processes can be confused with septic arthritis. Metaphyseal osteomyelitis may mimic septic arthritis because the adjacent joint may develop an effusion, and the two infections can be concurrent. Juvenile rheumatoid arthritis is usually more gradual in onset and produces polyarticular arthritis in children younger than 16 years but may be manifested as a monoarticular process that mimics septic arthritis. Toxic or transient synovitis, an inflammatory process common in children, especially after an upper respiratory infection, can be confused with septic arthritis. It occurs in the 3-month to 6-year age range, usually affects the hip, and is a self-limited disease, with no long-term morbidity. Children with transient synovitis have less pain with passive joint motion than patients with septic arthritis; they do not usually have a fever or appear ill but tend to favor the unaffected leg, as in septic arthritis. The diagnostic evaluation typically reveals a normal WBC count and ESR and no radiographic abnormalities.

Other diseases of the hip in children that are included in the differential diagnoses are Legg-Calvé-Perthes disease (avascular necrosis of the femoral head) and slipped capital femoral epiphysis; however, these processes are not as acutely disabling as septic arthritis. Rheumatic fever commonly presents with a migrating polyarthritis and may mimic gonococcal bacteremia. Patients with Lyme arthritis are not as debilitated as those with septic arthritis but, in endemic areas, serum antibody titers should be determined during evaluation of the patient with an effusion.

In the adult, osteoarthritis, gout, and pseudogout may produce findings on joint examination similar to the findings of septic arthritis. Other arthropathies, such as psoriatic arthritis, arthritis associated with inflammatory bowel disease, ankylosing spondylitis, crystal-induced arthritis, and drug-induced arthritis should also be considered in the differential diagnosis of septic arthritis. Collectively, these are known as the seronegative spondyloarthropathies. Trauma to the joint can produce synovitis and hemorrhatosis, which may be mistaken for septic arthritis. In a patient with hemophilia, hemorrhatosis causes joint inflammation and destruction, and there may be superimposed infection.

Reactive arthritis has traditionally been considered to be a sterile inflammatory response to a distant infection. However, antigens from the infectious trigger are often present in the joint. Several viral and bacterial microorganisms can produce reactive arthritis. The most recognized syndrome is poststreptococcal reactive arthritis. Some other common organisms that cause reactive arthritis are *Chlamydia, Salmonella, Shigella, B. burgdorferi* (Lyme disease), *Yersinia*, human T-lymphotropic virus type 1, rubella virus, hepatitis B virus, adenoviruses, parvovirus, and Epstein-Barr virus. Reactive arthritis can usually be distinguished from septic arthritis because it tends to involve multiple joints in a migratory pattern, the inflammatory process is less severe with reactive arthritis, there is less effusion, the joint is not as hot or tender as it is with septic arthritis, and joint fluid cell counts are usually below 50,000 cells/mm³.

Diagnostic Testing

**Serum and Urine Tests**

Blood tests are not consistently helpful in making a diagnosis of septic arthritis. Serum leukocytosis is nonspecific and nonsensitive for diagnosis of septic arthritis. Traditionally, a serum WBC count more than 10,000 cells/mm³ may suggest a systemic illness but is present in only 50% of patients with septic arthritis, and many sterile inflammatory processes create a similar leukocytosis. The ESR is elevated in approximately 90% of cases and, along with the CRP level, can be used to help diagnose the infection and track resolution. When low thresholds are used in the ED, the sensitivity of ESR is reported to be 98%, with a cutoff of 10 mm/hr or more, and the sensitivity of CRP is 92%, with a threshold of 20 mg/L or more. A sensitivity of 96% for an ESR higher than 30 mm/hr has been demonstrated. A procalcitonin level more than 0.5 ng/mL is another possible serum marker for septic arthritis, but is also nonspecific and is often not readily available in the ED.

Two sets of blood culture specimens should be obtained; however, blood cultures reveal the infecting organism in only 25% to 50% of cases. Cultures of infectious foci, such as the throat, cervix, and urine, may demonstrate the bacteria responsible for septic arthritis. Urine leukocyte esterase has been studied as a possible new indicator for a septic arthritis; it is especially sensitive and specific in prosthetic joints, with initial studies showing a high sensitivity and specificity.

**Joint Fluid Analysis**

The diagnosis of septic arthritis requires joint fluid for culture and analysis. It is fortunate that the knee joint is the most likely to be infected and the easiest to aspirate. Aspiration of other joints, such as the hip, usually requires interventional radiology or orthopedic surgical consultation. When violating the joint capsule, septic arthritis is the most likely to have an infected and the easiest to aspirate. Aspiration of other joints, such as the hip, usually requires interventional radiology or orthopedic surgical consultation. When violating the joint capsule, septic arthritis is the most likely to occur.

The definitive test to determine bacterial arthritis is synovial culture. When only a small volume of synovial fluid is recovered from a joint aspiration, the single most important test is a bacterial culture. Culture of the synovial fluid or of synovial tissue itself, obtained by arthroscopy, is the only definitive method for the diagnosis of infectious arthritis. If extra fluid is available after a culture specimen is obtained, other tests can be performed.

Gram stain, synovial WBC count and differential, percentage of polymuclear cells, crystal analysis, and joint fluid glucose level have traditionally been used to differentiate bacterial arthritis
from other joint diseases. Other tests of the synovial fluid are commonly performed, but many studies have refuted the efficacy of other additional tests.

Even with an adequate joint fluid sample, proper culture techniques, and the presence of fastidious organisms, synovial Gram staining results in clinically suspected septic arthritis are negative about one-third of the time, likely due to the planktonic state of the bacteria in the joint. A positive result of Gram staining can be used to guide antibiotic treatment; however, empirical treatment should not be delayed if the result is negative because Gram staining has a 45% to 71% false-negative rate.

Traditionally, a synovial fluid leukocyte count of more than 50,000 cells/mm³ with a predominance of polymorphonuclear leukocytes was used to define septic arthritis, but other processes can produce similar cell counts. Up to 30% of patients with septic arthritis have been documented to have counts well below 50,000 cells/mm³.

Many studies have supported the idea that a specific range of elevation of the synovial fluid leukocyte count can be reliably used to diagnose septic arthritis. One large study found that for a synovial fluid WBC count higher than 17,500 cells/mm³, the sensitivity was 83% and specificity was 67%. The positive likelihood ratio at this level was 2.5, with a negative likelihood ratio of 0.25. A synovial fluid leukocyte differential count with at least 90% neutrophils suggests septic arthritis, with a likelihood ratio of 3.4; a count of less than 90% decreases the likelihood ratio. There is mounting evidence that one cannot rely solely on the synovial fluid leukocyte count to exclude or include the diagnosis of septic arthritis; that this value should be used with the clinical, radiographic, and laboratory findings to help guide therapy as Grams staining and culture results become available.

The examination of synovial fluid under polarizing microscopy for the presence of crystals may be useful in the differentiation of inflammatory from noninflammatory joint disease but is not helpful in identifying infection in this population because the two often coexist. The identification of crystals should not deter the emergency clinician from continuing to search for an infectious cause of the joint pain.

Imaging

Plain radiography is not an effective tool for the early evaluation of septic arthritis but may detect surrounding osteomyelitis. In most joints, the small areas of attachment of the synovial membrane to bone are devoid of cartilage. These so-called bare areas at the margins of the joint appear as lucencies or erosions early in the course of septic arthritis. Bone beneath the articular cartilage may start to erode 1 to 3 weeks into the disease. Air in the joint may be a sign of infection with gas-forming organisms but may be the result of a previous joint aspiration. In patients with existing joint disease, radiographs provide minimal assistance in the diagnosis of septic arthritis.

For joints that are not visualized, other than a physical examination, a variety of modalities are available to help detect a joint effusion, which under the right circumstances could suggest septic arthritis. However, the differential diagnoses for a joint effusion is long, and aspiration of the fluid must be done to make the diagnosis. Ultrasonography is a useful modality to help detect a joint effusion and assist in joint aspiration, particularly of the hip (Fig. 128.9). CT and MRI can identify joint fluid but not necessarily an effusion, because a volumetric analysis cannot be done to assess the amount of fluid. In adult patients with an antalgic gait and painful internal and external rotation of the hip, MRI findings of bone marrow edema led to a diagnosis of septic arthritis only 6% of the time. Other conditions that cause bone marrow edema include reactive arthritis, transient osteoporosis, avascular necrosis, osteoarthritis, tuberculous arthritis, osteomyelitis, sickle cell anemia, lymphocytic leukemia, and femoral stress fracture and should be considered.

CT and MRI provide detailed anatomic images of the joint, and MRI can also help determine if septic arthritis is complicated by concurrent osteomyelitis. Skeletal scintigraphy (bone scanning) has been used in the diagnosis of septic arthritis, but its use has been decreasing. The main advantage of skeletal scintigraphy is for the detection of septic arthritis earlier than with other imaging techniques. In septic arthritis, scintigraphy shows symmetric areas of increased uptake on both sides of the joint. In a three-phase ⁹⁹mTc scan, all three phases will be hot with septic arthritis. In general, skeletal scintigraphy is used only when there is enough uncertainty about the diagnosis to warrant further investigation, such as in the hip joint. In joints in which aspiration is easier, skeletal scintigraphy has little role in diagnosis.

Management

Septic arthritis is an orthopedic emergency and, once synovial fluid is obtained, empirical antibiotics should be promptly administered on the basis of Gram stain results, when possible, if the diagnosis is strongly suspected (Table 128.4). Whereas most joint infections require surgical joint decompression, there are a few cases in which medical management will suffice, such as with gonococcal septic arthritis and Lyme arthritis.

Unlike most other infectious emergencies encountered in the ED, when time to antibiotic administration decreases morbidity and mortality, definitive management for most cases of septic arthritis requires surgical intervention and a prolonged course of antibiotics. Therefore, it is more important to obtain synovial fluid for Gram staining and culture than to start antibiotics, because this will guide long-term antibiotic treatment. In the hemodynamically stable patient in whom septic arthritis is a strong consideration, antibiotics should be held until blood and synovial fluid cultures are obtained.
Elderly patients, those with preexisting joint disease, and those with severe immunosuppression have a higher risk of developing septic arthritis.

### Diagnosis

The diagnosis of septic arthritis is challenging because symptoms can be non-specific, and definitive laboratory tests may not be available for several hours. The diagnostic criteria for septic arthritis include:

- Fever
- Pain
- Swelling
- Joint effusion
- Tenderness

### Treatment

**Antibiotics** are the cornerstone of treatment. The selection of antibiotics is based on the suspected pathogen and the patient's risk factors. Common pathogens include Staphylococcus aureus, Streptococcus, and enteric gram-negative bacilli.

- **S. aureus:** Usually sensitive to beta-lactams (e.g., nafcillin, oxacillin, or vancomycin) and vancomycin is reserved for MRSA.
- **Enteric gram-negative bacilli:** Often resistant to beta-lactams and require a combination of antibiotics, such as aminoglycosides and fluoroquinolones.
- **Streptococci:** Often sensitive to penicillin G, amoxicillin, or clindamycin.

### Disposition

Patients with suspected septic arthritis require immediate clinical evaluation, including joint aspiration and blood cultures. In critically ill patients, empirical antibiotics should be started before results are available. In most cases, treatment is initiated as soon as possible to prevent the progression to joint destruction and joint replacement.

**KEY CONCEPTS**

- Skeletal infection should be considered in the differential diagnosis of all patients with bone or joint pain.
- Hematologic evaluation is of little value in the diagnosis of bone and joint infections, with the exception of the ESR and CRP level, which are elevated in approximately 90% of cases of bone and joint infections.
- The diagnostic evaluation for septic arthritis includes complete blood count, ESR, and CRP level. Joint aspiration is the definitive diagnostic procedure, and synovial culture is the only reliable joint fluid test for establishing a diagnosis.
- The diagnosis of osteomyelitis involves an operative culture of the infected bone. MRI has become the best diagnostic modality to detect osteomyelitits.
- With suspected septic arthritis, joint fluid and blood culture specimens are obtained before IV antibiotics are administered. With suspected osteomyelitits, bone blood culture specimens are obtained, and IV antibiotics are administered while plans are made for further imaging studies or surgical aspiration or resection of bone.
- The most important aspect of antibiotic treatment of suspected bone and joint infections is to provide potent bactericidal activity against *S. aureus* with additional empirical antibiotic coverage aimed at suspected organisms on the basis of age, risk factors, and regional variability.

CHAPTER 128: QUESTIONS & ANSWERS

128.1. Which of the following statements regarding osteomyelitis is true?
A. Contiguous focus osteomyelitis is most common in the knee.
B. Hematogenous osteomyelitis begins in medullary bone.
C. Head and neck osteomyelitis is usually from hematogenous spread.
D. Septic arthritis begins in joint fluid and spreads to synovium.
E. Septic arthritis morbidity is related to joint size.

Answer: B. Hematogenous osteomyelitis begins in medullary bone and spreads outward. Contiguous focus osteomyelitis, most common in the foot and hand, begins outside of bone and spreads inward via Volkmann's canal. Head and neck osteomyelitis is usually from a contiguous sinus or otic process. Septic arthritis begins in synovium and later involves joint fluid. Morbidity is related to the degree of hyaline cartilage destruction.

128.2. Which of the following associations between osteomyelitis and pathogenic organism is true?
A. Dog bite—Pasteurella
B. Freshwater wounds—Pseudomonas
C. Human bite—Aeromonas
D. Intravenous drug use—Fusobacterium
E. Sickle cell anemia—Haemophilus influenzae

Answer: A. The following are correct associations:
Freshwater—Aeromonas hydrophila
Intravenous drug use (IVDU)—Staphylococcus aureus
Sickle cell—Pseudomonas and Salmonella
Cat or dog bite—Pasteurella multocida
Human bite—mixed with Fusobacterium, Eikenella, and Streptococcus anginosus

128.3. Which of the following statements regarding septic arthritis is true?
A. Despite vaccination, Haemophilus influenzae remains a frequent pathogen in children.
B. Pseudomonas aeruginosa is associated with IVDD-related osteomyelitis.
C. Pseudomonas aeruginosa is not associated with prosthetic device joint infection.
D. The most common organism in neonates is Staphylococcus aureus.
E. The most common organism in patients younger than 30 years is S. aureus.

Answer: B. Pseudomonas is associated with IVDD-related cervical osteomyelitis and lumbar osteomyelitis in cases of prolonged urinary catheterization. H. influenzae has largely disappeared as a joint pathogen in vaccinated children. The most common neonatal joint pathogens are group B streptococci, Escherichia coli, and Staphylococcus epidermidis. The most common cause of septic arthritis in people younger than 30 years is gonococcal.

128.4. Which of the following statements regarding acute hematogenous osteomyelitis in children is true?
A. Blood cultures are not usually positive.
B. Skeletal scintigraphy is indicated in neonates.
C. The child usually appears toxic.
D. The most common site is the long bone epiphysis.
E. There is a female preponderance.

Answer: C. Children may be ill but not usually toxic. There is a 2:1 or 3:1 male predominance, with the most likely site being the distal metaphysis. Blood cultures are positive in 60% of cases. Scintigraphy is not useful in neonates due to a limited inflammatory response. Radiographs are more useful and sensitive early on in adults.
128.5. Which of the following statements regarding vertebral osteomyelitis is true?
   A. Children are less prone to isolated diskitis.
   B. Of the cases of epidural abscesses, 30% are due to osteomyelitis.
   C. The diagnostic procedure of choice is a magnetic resonance imaging scan.
   D. The most common location is the lumbar spine.
   E. Vertebral osteomyelitis typically involves a single vertebra.

   **Answer:** D. The incidence of associated epidural abscess is 15%. The most common location of vertebral osteomyelitis is the thoracic, lumbar, and cervical spine. The diagnostic procedure of choice is needle biopsy. The disease usually involves two vertebrae and the disk in between. Children are more prone to isolated diskitis, although it may also occur in adults.

128.6. An 18-year-old woman with known sickle cell disease presents with leg pain of 2 days’ duration. Her typical pain syndrome is lower extremity tibial and femur pain. Today’s episode is primarily right tibial. She complains bitterly of pain, but there are no gross findings other than trace bilateral anterior tibial swelling, with no discernible warmth or erythema. Vital signs are remarkable for a low-grade fever and heart rate of 110 beats/min. Which of the following statements regarding this patient’s condition is true?
   A. Bony infection would be expected in the bony diaphysis.
   B. Plain radiography can differentiate bony infarction from infection.
   C. *Salmonella* would be the most likely infectious cause.
   D. Technetium scintigraphy (bone scanning) will differentiate infection from infarction.
   E. The erythrocyte sedimentation rate (ESR) is elevated in sickle pain crises.

   **Answer:** A. Sickle cell osteomyelitis is more typically seen in the diaphysis than in non–sickle cell situations, which more often involve the metaphysis. Fever, toxicity, and an elevated ESR suggest infection. The most likely infectious cause is still *Staphylococcus aureus*, followed by *Salmonella*. Often, observation and response to therapy (eg, analgesics, hydration) ultimately help differentiate the two. Plain technetium lights up infection and infarction. Indium or gallium is necessary to show a hot spot of infection; an infarctive site would be cold.

128.7. Which test will most likely confirm a diagnosis of gonococcal arthritis in a female?
   A. Pelvic culture
   B. Serum gonococcal culture
   C. Synovial gonococcal culture done on chocolate agar
   D. Thorough history

   **Answer:** A. It is recommended that cervical culture be used to confirm the likely presence of GC arthritis.

128.8. When should antibiotics be administered in cases of suspected septic arthritis?
   A. After radiographic confirmation of the diagnosis
   B. After serologic confirmation of the diagnosis
   C. After synovial fluid is sent for culture
   D. After synovial Gram staining comes back positive

   **Answer:** C. To guide effective antibiotic therapy, it is recommended to withhold antibiotics until synovial fluid has been obtained.
Skin Infections

Daniel J. Pallin

PRINCIPLES

Background and Importance

Skin and soft tissue infections run a gamut from mild conditions such as cellulitis, abscess and fungal infections to more severe conditions with high mortality, despite modern therapy, such as necrotizing fasciitis and toxic shock syndromes.

The epidemiology of skin infections has changed significantly over the past 2 decades with the emergence of a new organism—community-associated methicillin-resistant *Staphylococcus aureus* (CA-MRSA). Abscesses became more common and accounted for an increasing proportion of emergency department (ED) visits until the epidemic stabilized, around 2010. More recently, attention has turned from the threat of CA-MRSA to the threat of antibiotic overuse because studies have found no benefit from antibiotic treatment of abscesses and no benefit from targeting CA-MRSA in cellulitis.

Anatomy and Physiology

The skin is the largest organ in the body and accounts for about 15% of total body weight. It has three layers, the hypodermis, dermis, and epidermis (Fig. 129.1). Hair is present throughout the body except on glabrous skin, which is the heavily keratinized skin found on the palms, soles, and parts of the genitals.

The skin has a rich supply of blood vessels, lymphatics, and nerves, although the epidermis is entirely avascular and relies on the dermis for nourishment. The main cell type in the epidermis is the keratinocyte, which has a cytoskeleton composed of keratin filaments, which are proteins. Also living in the epidermis is the Langerhans cell, a motile, macrophage-like, antigen-presenting member of the immune system that originates in the bone marrow. Melanocytes in the epidermis produce melanin in response to ultraviolet light—induced DNA damage.

The epidermis contains the pilosebaceous follicles and sweat glands, known collectively as epidermal appendages. The combination of the hair apparatus and sebaceous gland is known as a pilosebaceous follicle. The epidermal appendages are important as sites of infection because they provide a break in the otherwise continuous protective layer of keratinocytes and create a potential space for bacterial replication. There are two types, sweat glands and follicles. Sweat glands take three forms—eccrine, apocrine, and apocrine, and apocrine.

The dermal-epidermal junction is a complex basement membrane whose disruption results in vesicles and bullae. The dermis consists of cells, fibers, and ground substance, which is an acellular material composed of glycoproteins and other macromolecules. The hypodermis, or subcutaneous tissue, is composed largely of adipocytes. The lymphatic system drains interstitial fluid, and its disruption leads to interstitial fluid accumulation and edema.

Pathophysiology

The source of a skin infection may not always be evident. Many skin infections arise from breaks in the protective epidermal layer, such as a cut, injection, or abrasion, known as portals of entry. Hematogenous seeding from another infected site is another possible source. Often, the source is not clear. Venous blood and lymph drain from the orbits and skin around them into the cavernous sinuses; thus, bacterial infections in this area can lead to central nervous system infection.

Clinical Features

Most skin infections present with redness (erythema), warmth, and induration. Erythema can be difficult to see in darkly pigmented people. It is caused by microvascular dilation due to the immune response. Confluent erythema is typical of most skin infections; discrete macules and morbilliform (measles-like) eruptions are not typical. Induration simply means hardening and is a common finding with many inflammatory lesions of the skin. Skin that is indurated because of cellulitis sometimes becomes engorged with interstitial fluid and takes on the texture of an orange peel due to dimpling where the skin is anchored by hair follicles. This classic finding is known by the French phrase *peau d'orange*—that is, orange peel skin.

Fluctuance describes a fluid collection palpated on examination. “Pointing” or “coming to a head” conveys a sense of imminent rupture. Crepitance describes skin that feels crackly when it is palpated and suggests that gas is present in the soft tissues. This suggests necrotizing infection, discussed later.

Fever is present in 50% of patients with bacterial skin infections presenting to the ED. Febrile skin infections are more common in children; in adults, fever may indicate a more serious infection.

Many skin infections have characteristic appearances. Well-demarcated erythema with a raised border, particularly on the face, is typical of erysipelas, a streptococcal cellulitis. Linear erythema tracking distally to proximally along a vascular pathway suggests lymphangitis or phlebitis and usually represents the action of cytokines involved in combating the infection, although proximal spread of the infection itself is a possibility.

Less common color changes associated with infection stem from small hemorrhages, vasculitis, or septic emboli. Janeway’s lesions are painless red, purple, or brown spots, usually seen on the hands or feet, due to septic emboli from infective endocarditis. Painless discolorations of the palms and soles should also trigger concern for secondary syphilis or Rocky Mountain spotted fever.

When the diagnosis of infection is not clear, vasculitides such as Kawasaki syndrome in children and Wegener’s granulomatosis should be considered. Petechiae and purpura can indicate overwhelming bacterial infection, as with meningococcemia. Vesicles suggest contact dermatitis, herpes simplex, variella-zoster, or impetigo. Intracutaneous pustules on the palms or soles of the feet are often due to a form of psoriasis called palmoplantar pustulosis, which is troublesome but benign.

Pruritic serpiginous (snakelike) lesions that are not particularly tender suggest an intracutaneous parasite, such as scabies (hands, intertriginous areas), hookworm larvae (feet or buttocks), or strongyloidiasis. Parasitic nematodes (eg, Guinea worm) and insects (eg, botfly) should be considered in the setting of
a nodule after exposure to fresh water or insects in developing countries.

Skin infections can suggest underlying systemic illness. For example, a young man who presents with a first episode of balanitis may have diabetes as the underlying problem. Disseminated varicella (other than a first episode of chickenpox) suggests immunocompromise.

DIFFERENTIAL DIAGNOSIS AND DIAGNOSTIC TESTING

Wound Cultures

For cellulitis and abscess, the only relevant laboratory test is a wound culture and Gram staining when pus is present. However, there has been debate about the necessity of obtaining culture specimens from skin infections. Advocates of culturing abscesses view the procedure as inexpensive and specific. Opponents view it as an unnecessary inconvenience that is unlikely to change management; they also are concerned that cultures may be biased toward detection of robust aerobes such as *Staphylococcus* and against detection of anaerobes and fastidious organisms. I recommend culturing complicated purulent infections, such as surgical wound infections that may involve deep structures or abscesses in immunocompromised patients. Uncomplicated skin abscesses are usually caused by CA-MRSA, and culture is not required. However, in the setting of diagnostic uncertainty, as with abscesses associated with animal bites, which may be caused by *Pasteurella multocida* or CA-MRSA, I recommend Gram staining as soon as possible. Nonpurulent cellulitis is not routinely cultured.

Blood Cultures

Blood cultures are not indicated in patients with skin infection, except in cases where deep tissue infection or systemic infection is likely, such as septic shock, necrotizing infections, immunocompromise, multifocal infections suggesting hematogenous seeding, and infections complicating lymphedema.

Early studies had found pediatric facial cellulitis often to be accompanied by *Haemophilus influenzae* bacteremia. However, the relevant strain is type b, which is now covered by childhood vaccination. Moreover, this organism is typically targeted presumptively in the treatment of facial cellulitis, and there is no evidence that blood culture is of benefit. In fully vaccinated children and adults with facial cellulitis, I do not recommend blood culture as long as an agent effective against *H. influenzae* (eg, cephalexin, amoxicillin-clavulanic acid) is used.

Radiographic Studies

When a foreign body is suspected, plain radiographs are traditionally obtained, although they occasionally miss foreign bodies that are small or radiolucent. Ultrasonography has also been promising for the detection of foreign bodies. The location and extraction of foreign bodies can be challenging, and emergency clinicians must use their judgment in deciding when to use plain films, ultrasound, or both.

For necrotizing infection, plain radiographs or computed tomography (CT) may reveal soft tissue gas or inflammation along fascial planes, but cannot rule out necrotizing infection. Ultrasonography examination is useful for differentiating abscess from cellulitis, as discussed later.

Plain radiographs are used to evaluate for evidence of osteomyelitis for chronic skin infections, especially in patients with diabetes, peripheral vascular disease, and secondarily infected nonhealing ulcers. Plain films are not definitive, and bone scanning and magnetic resonance imaging (MRI) have higher sensitivity for detecting osteomyelitis. CT is helpful when there is concern that a skin infection is actually an extension of a deeper infection, such as after surgery or in the case of recurrent perianal abscesses.

Other Diagnostic Tests

Skin scrapings for microscopy are key to the accurate diagnosis of some infections, including scabies, varicella, herpes simplex, tinea, candidiasis, and leishmaniasis. When necrotizing infection is clinically suspected, operative exploration by a surgeon is considered the definitive rule-out procedure.

CELLULITIS

Principles and Clinical Features

Cellulitis is an inflammatory condition of skin and subcutaneous tissue thought to be the result of bacterial infection. Cellulitis may be purulent or nonpurulent and may occur in the setting of wounds, foreign bodies, or impaired perfusion. Purulent cellulitis drains freely, in contrast to abscesses, which are walled off by fibrous tissue and epidermis. CA-MRSA is the leading cause of purulent skin and soft tissue infections in ED patients, but its role in nonpurulent cellulitis is unknown.

The cardinal feature of cellulitis is inflammation due to increased local blood flow. In darkly pigmented patients, inflammation may be subtle. Pain may be variable, but some experts believe that all cases are tender (in patients without neuropathy). The inflammation of cellulitis is typically confluent, although it may be patchy. The borders are typically poorly defined and irregular. Linear or circular lesions should prompt a search for other underlying causes, such as contact dermatitis or Lyme disease. In some cases of cellulitis, there are streaks of inflammation extending proximally from the main area of inflammation, along vascular tracts. This finding is known as lymphangitis and is commonly seen with cellulitis due to streptococci and bite wound–associated *Pasteurella multocida*.

When localized edema becomes severe, epidermal layers can separate, leading to vesicles or bullae. This can make it difficult to distinguish cellulitis from other infectious and noninfectious causes of dermatitis. When the border of an area of cellulitis becomes well demarcated, raised, and palpable, the term *erysipelas* is used. This form of cellulitis is most often caused by *Streptococcus pyogenes*. The bacterial causes of cellulitis vary according to body site, comorbidities, and environmental exposures (Table 129.1).
Diabetic Foot Infections

Diabetic foot infections are the most common cause of hospitalization for patients with diabetes, and an infected wound precedes two-thirds of lower extremity amputations in patients with diabetes. Neuropathy, vascular insufficiency, and hyperglycemia are important factors in the development of diabetic ulcers and foot infections. Although early antibiotic therapy is important in diabetic infections, it is important to avoid antibiotic overuse, and uninfected ulcers should not be treated with antibiotics.

The most likely organisms in an acute diabetic foot infection are *S. aureus* and streptococci. Chronic wounds are more likely to be polymicrobial with gram-positive and gram-negative organisms, as well as anaerobes. Chronic wounds that have previously been treated with antimicrobials are more likely to involve multidrug-resistant organisms. *Pseudomonas* is a traditional concern but is uncommon. Deep tissue specimens for aerobic and anaerobic culture or bone samples should be obtained at the time of débridement if deep tissue infection or osteomyelitis is suspected. Organisms cultured from superficial swabs are not reliable for identifying pathogens responsible for deeper infection. Osteomyelitis should be considered a potential complication of any deep or extensive ulcer, especially one that is chronic or overlies a bony prominence. In addition to antibiotics, diabetic foot infections require careful wound care and, in some cases débridement, revascularization, or amputation.

**Bite Wounds**

A high proportion of cat bites become infected, and presumptive antibiotic treatment is appropriate in the absence of signs of infection. The typical agent is *P. multocida*. Human bites also become infected frequently, and oral anaerobes such as *Bacteroides* are typical. Dog bites become infected infrequently, and only severe wounds and sutured wounds require antibiotics. Amoxicillin–clavulanic acid is an appropriate agent for cat and human bites and for infected or sutured dog bites.

**Water-Borne Infections**

Exposure and travel history are important considerations in the evaluation of skin and soft tissue infections. *Vibrio* spp., in particular *V. vulnificus*, are associated with exposure to seawater and can cause severe soft tissue infections and septicemia. Patients with liver disease, such as cirrhosis, are particularly at risk. Infection occurs from contamination of open wounds by seawater or shellfish and rarely by hematogenous spread from the ingestion of contaminated seafood, such as raw oysters. *Edwardsiella tarda* is a rare cause of wound infection after seawater exposure; it has been implicated in serious soft tissue infections, including myonecrosis, particularly in patients with liver disease. *Erysipelothrix rhusiopathiae* is usually associated with a localized erysipeloid eruption with minor trauma, often on the hands of seafood workers.

*Aeromonas* myonecrosis is associated with exposure to fresh water by penetrating trauma or exposure to aquatic animals. It causes rapidly progressive suppurrative infections that often require surgical drainage. *Mycobacterium marinum* causes so-called fish tank granuloma. It typically is manifested weeks after exposure as a papule or nodule that may ulcerate and drain serosanguineous fluid. Multiple nodular lesions may develop along lymphatics.

*For life- or limb-threatening infections, use IV equivalents and add vancomycin. CA-MRSA, Community-associated methicillin-resistant Staphylococcus aureus.*
Differential Diagnosis and Diagnostic Testing

When lymphangitis and fever are present, a bacterial infection is probable. In the absence of these signs, other possibilities include contact dermatitis, fungal infection, burns, viral infections, and allergies, including fixed drug eruptions, which can manifest with localized inflammation. Cellulitis must be distinguished from more severe necrotizing infections, as discussed later.

Consider Lyme cellulitis in endemic areas. Lyme disease causes a typical rash known as erythema chronicum migrans. It is a bright red, round lesion, usually larger than 5 cm, with central clearing that gives it a targetoid appearance. It occurs in only 80% of cases of Lyme disease. When the rash is observed in an endemic area, Lyme disease can be diagnosed and treated without further testing. Other insect-bite–associated skin infections can occur, such as cellulitis and abscess; however, insect bite reactions are frequently mistaken for infections, and this possibility should be considered before initiation of antibiotics.

Needle aspiration and even biopsy of cellulitis lesions are unlikely to reveal the cause and are not recommended. Blood cultures are not recommended except in the presence of a presumed hematogenous source of infection, in septic shock, and in cellulitis complicating lymphedema. Blood cultures are also traditional for facial cellulitis but may be omitted in well-appearing patients who are treated with agents active against *H. influenzae*. The role of high-sensitivity pathogen identification, such as polymerase chain reaction analysis of surface skin swabs, has yet to be determined.

Venous stasis dermatitis is similar in appearance to cellulitis but is not infectious in origin. It is typically located above the ankle and is often (but not always) circumferential. When above-ankle dermatitis is accompanied by fever, cellulitis may be present, but other causes of fever should be sought, especially if the inflammation is bilaterally symmetric. Symmetric venous stasis dermatitis in the afebrile patient should not be confused with cellulitis. When there is inflammation near a joint, the differential diagnosis includes gout, pseudogout, septic arthritis, tenosynovitis, ruptured Baker’s cyst, traumatic joint effusion, hemorrhage, and autoimmune arthritis.

Management

Emergency clinicians have changed their prescribing practices dramatically since CA-MRSA was first described. In 1993, antibiotics targeted to CA-MRSA were almost never prescribed for skin and soft tissue infections. By 2005, 38% of antibiotic regimens included an agent typically active against CA-MRSA; however, multiple studies have shown that antibiotics do not make a difference in the treatment of abscess. Only one trial has evaluated the effectiveness of agents targeting CA-MRSA in cellulitis, and this trial found no treatment benefit. I recommend that cellulitis be treated with cephalexin or an equivalent β-lactam. Penicillin-allergic patients may take β-lactams unless they had anaphylaxis or another life-threatening allergy, in which case clindamycin is the recommended alternative.

Table 129.2 summarizes relevant antibiotics. Oral agents with activity against CA-MRSA include trimethoprim-sulfamethoxazole (TMP-SMZ), clindamycin, tetracyclines, and linezolid. The common strains of CA-MRSA (ie, USA-300) are almost universally susceptible to TMP-SMZ in vitro. TMP-SMZ is well tolerated in most patients and adverse reactions (eg, Stevens-Johnson syndrome) are no more common than with other agents, such as ampicillin. However, TMP-SMZ is not considered effective against streptococci. Thus, when CA-MRSA is suspected but streptococci remain a possibility, we recommend TMP-SMZ plus a β-lactam such as cephalaxin, with clindamycin monotherapy being a good alternative.

Dicloxacillin is commonly suggested as an agent for treatment of cellulitis because of its appropriate spectrum and high potency. However, it must be taken four times daily on an empty stomach—a very challenging task—and causes gastrointestinal upset. Doxycycline is another option for coverage of CA-MRSA. However, this agent must also be taken on an empty stomach and also causes gastrointestinal upset. Moreover, it is not thought to cover streptococci well. As with TMP-SMZ, when doxycycline is prescribed for skin and soft tissue infections, a β-lactam should be added to target streptococci unless the cause of the infection is known. Doxycycline causes photosensitivity, and patients should be warned to avoid sun exposure.

Clindamycin has been used increasingly because most CA-MRSA isolates are sensitive to it, and it is an excellent agent for streptococci. CA-MRSA can become resistant to clindamycin during a single course of treatment. This phenomenon is termed *inducible resistance* and occurs in about 2% of CA-MRSA isolates. Most microbiology laboratories in the United States now test for inducible resistance among MRSA strains that are susceptible to clindamycin in vitro. The test for inducible resistance is known as the D-test. The name comes from a D-shaped pattern of the area of clindamycin’s inhibition of bacterial growth, which results from resistance induced by a pellet (disk) of erythromycin that is placed next to the clindamycin pellet.

Early reports of susceptibility of CA-MRSA to rifampin gave way to later reports of widespread resistance, inducible and de novo. This agent is not recommended for skin infections.

Vancomycin is the standard parenteral agent for MRSA. Others include linezolid, daptomycin, tigecycline, and telavancin. No penicillin or cephalosporin is active against CA-MRSA, except ceftaroline, a parenteral cephalosporin approved by the US Food and Drug Administration in 2010 and indicated for complicated skin infections.

The first-line agent for treatment of nonpurulent cellulitis is cephalexin, which is safe, well tolerated, and well absorbed, and need not be taken on an empty stomach. Relatively severe infections are commonly managed with one or more initial doses of the intravenous (IV) equivalent cefazolin, which, like cephalexin, is given in maximal doses (eg, 2 g tid for adults); there is insufficient evidence to recommend for or against this practice. Nafcillin is an equivalent option. In patients allergic to cephalexin, clindamycin is an excellent choice. Table 129.1 provides further treatment recommendations. Agents effective against CA-MRSA are not recommended for nonpurulent skin infections, except in cases not initially responsive to first-line therapy or when septic shock is present.

Adjunctive measures are important in the treatment of cellulitis, according to expert opinion, but without evidentiary support. Extremity cellulitis responds dramatically to compression and elevation. The extremity should be elevated above the level of the heart. A splint is useful as an anchor for elevation and can be hung from an IV pole. Patients with cellulitis complicating venous stasis or lymphedema should be educated about the importance of compression with elastic socks, sleeves, or wraps. This is helpful for the acute infection and also to prevent future episodes. Nonsteroidal antiinflammatory drugs (NSAIDs; eg, ibuprofen) are helpful, and I recommend them in the absence of contraindications.

Fig. 129.2 is a universal treatment algorithm for skin and soft tissue infections. The algorithm assumes no prior treatment and no toxic shock syndrome. Previously treated infections require broader spectrum antibiotic coverage and customized management decisions.
### Disposition

Immunocompetent patients with cellulitis who can be trusted to adhere to recommended medications and adjunctive measures can be managed as outpatients. In severe cases, such as those with fever or more extensive infection, one or more initial IV doses are often given in the ED. Hospitalization is generally required for immunosuppressed patients and patients with diabetic foot infections, infected lymphedema, and multifocal cellulitis or suspected necrotizing infection.

### ABSCESS

#### Principles and Clinical Features

An abscess begins when bacteria multiply in the lumen of a hair follicle or at other locations beneath the epidermis. Neutrophils are drawn to the site of infection, and various cytokines combine with bacterial toxins to promote the development of purulence. The overlying epidermis prevents drainage. A painful red mass is usually seen; it may be tender and often is warm. Skin abscesses are rarely fatal, and most will eventually rupture through the epidermis and drain spontaneously. Historically, abscesses were usually caused by methicillin-sensitive *S. aureus* or mixed flora but, by 2004, CA-MRSA accounted for 61% of abscesses in the United States.

Bartholin’s cyst abscess is caused by an obstructed Bartholin duct. Bartholin’s gland is located at the upper part of the lower third of the labium majus, and its duct opens onto the mucosa in this area medially but externally to the labium minus. Bacteria cultured are usually a mixture of aerobic and anaerobic flora from the vagina. *Chlamydia trachomatis* or *Neisseria gonorrhoeae* is isolated approximately 10% of the time.

A pilonidal abscess is an abscess at the superior aspect of the gluteal cleft between the buttocks. Also known as a pilonidal cyst, this abscess often recurs. Treatment is the same as for other cutaneous abscesses.

A stitch abscess is a collection of pus around a suture. Often, stitch abscesses are sterile, but a deeper wound infection can be confused with a stitch abscess.

#### Differential Diagnosis and Diagnostic Testing

The differentiation of abscess from cellulitis can be challenging. Bedside ultrasound examination is the best option. A high-frequency linear probe is used. Abscesses are seen as hypoechoic areas with posterior acoustic enhancement. The hypoechoic areas are pus and may be heterogeneous, with some bright signals (Fig. 129.3A). Cellulitis is seen as a uniformly hyperechoic area or as hyperechoic areas separated by curvilinear hypoechoic areas (see Fig. 129.3B). This appearance is known as cobblestoning and results from interstitial edema.

Necrotizing fasciitis, discussed below, is always a consideration, although it is extremely rare relative to cellulitis. Fistula should be considered when perianal or perivaginal infections are evaluated, and the mucosa should be examined digitally. When perirectal abscess recurs, a deep abscess may be the source, and external examination may be unreliable. In this case, CT scanning should be considered.

The epidermoid cyst represents another diagnostic challenge. These lesions, formerly known as sebaceous cysts, are benign cystic tumors resulting from the pathologic accumulation of keratinaceous material. Patients report a long history of a cutaneous mass, often intermittently painful. These lesions become inflamed periodically and sometimes rupture spontaneously. With rupture, they drain a pearly white or yellowish, glistening, waxy material. Pus, which appears dull and viscous rather than waxy, may indicate an infected epidermoid cyst. Isolated mild inflammation of an epidermoid cyst does not contraindicate primary excision, although primary excision is more difficult during an episode of inflammation. A brief course of antibiotics and NSAIDs with delayed excision is also an option.

Vascular aneurysms and enlarged lymph nodes can be misdiagnosed as abscesses. Ultrasound examination can be helpful in this regard, and a color Doppler study should be used to investigate perivascular abscesses. When there is doubt, needle aspiration should be used to confirm the presence of pus and absence of blood.

Inflamed cutaneous nodules and cystic masses in returning travelers and immigrants from developing countries present special diagnostic challenges. Typical staphylococcal abscesses are

*ADULT DOSE (mg) for children aged 2–8 years is the same as for adults.

**Nonantibiotic Adjuncts**

- **Surgical Excision:** Recommended for all abscesses except epidermoid cysts. Primary excision may be performed. When a deep abscess recurs, a fistula should be considered. In this case, CT scanning should be considered.

**Radiology**

- **Ultrasound:** Best option for bedside imaging. Abscesses are seen as hypoechoic areas with posterior acoustic enhancement. Cellulitis is seen as a uniformly hyperechoic area or as hyperechoic areas separated by curvilinear hypoechoic areas.

**Laboratory Tests**

- **Gram-Stain:** Provides immediate information about bacterial type and sensitivity.
- ** Cultures:** Sensitive and specific, but slow. May miss nonviable bacteria.
- **Cellulitis:** Cultures are usually negative. Leukocytosis and elevated erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) levels are typical.

**Medical Management**

- **Antibiotics:** For cellulitis, prophylactic antibiotics are not necessary. For abscesses, broad-spectrum antibiotics are required.

**Disposition**

- **Outpatient:** For immunocompetent patients with cellulitis who can be trusted to adhere to recommended medications and adjunctive measures.

**COMMONLY SEEN MAJOR CONTRAINDICATIONS**

- **Sulfamethoxazole–Trimethoprim:** Caution in renal impairment, blood dyscrasias, and sulfa allergy.

**COMMONLY SEEN MAJOR CONTRAINDICATIONS:**

- **Doxycycline:** Caution in pregnancy (category C).

**CLINICAL PEARLS**

- **Cellulitis:** Differentiation from abscess can be challenging. Ultrasound is the best option.

**DIAGNOSIS:**

- **Abscess:** Hypoechoic area with posterior acoustic enhancement.

**TREATMENT OPTIONS:**

- **Surgical Excision:** Recommended for all abscesses except epidermoid cysts. Primary excision may be performed. When a deep abscess recurs, a fistula should be considered. In this case, CT scanning should be considered.

**SPECIAL DIAGNOSTIC CHALLENGES:**

- **Necrotizing fasciitis:** Always a consideration. Requires early recognition and prompt treatment. Ultrasound is the best option for bedside imaging.

**OUTCOMES:**

- **Abscess:** Typically resolves with antibiotics and incision and drainage.

**PREVENTION:**

- **General Measures:** Good hygiene, wound care, and prevention of trauma. For infections in high-risk areas, prophylactic antibiotics may be indicated.

**REFERENCES:**

- **Mandell GL, Bennett JE, Dolin R, eds. Mandell, Douglas, and Bennett’s Principles and Practice of Infectious Diseases. 8th ed. Philadelphia: Elsevier; 2019:**

**ABSTRACT:**

- **Cellulitis:** Differentiation from abscess can be challenging. Ultrasound is the best option. Abscesses are seen as hypoechoic areas with posterior acoustic enhancement. Cellulitis is seen as a uniformly hyperechoic area or as hyperechoic areas separated by curvilinear hypoechoic areas.

**KEY POINTS:**

- **Cellulitis:** Differentiation from abscess can be challenging. Ultrasound is the best option. Abscesses are seen as hypoechoic areas with posterior acoustic enhancement. Cellulitis is seen as a uniformly hyperechoic area or as hyperechoic areas separated by curvilinear hypoechoic areas.
most common, but parasitic causes, such as dracunculiasis and myiasis, should be considered.

Management
The treatment of abscess is surgical, and antibiotics are usually not indicated. Exceptions for which antibiotics may be beneficial include severe or extensive disease (eg, involving multiple sites of infection), severe associated cellulitis, signs and symptoms of systemic illness, associated comorbidities or immunosuppression, extremes of age, abscess in an area difficult to drain (eg, face, hand, genitalia), septic phlebitis, and poor response to incision and drainage alone. Needle aspiration alone has not been found to be an adequate alternative to incision and blunt dissection.

Abscess incision and drainage is a nonsterile procedure, but the operator and all environmental fomites should be protected from contamination and transmission of MRSA. The main challenge is to attain adequate analgesia. Injection of local anesthetics into the skin overlying an abscess is difficult because the skin is usually edematous and tense. Also, superficial anesthesia is often inadequate for blunt dissection. An alternative is to administer procedural sedation. Another excellent option is regional anesthesia (nerve block). Oral analgesia plus a ring block may also provide adequate anesthesia and analgesia. The following medications are safe together and have additive effects: ibuprofen, acetaminophen, oxycodone, and low-dose diazepam. The ring block is performed with a 25-gauge needle (3.5-inch spinal needle for large areas) to inject bupivacaine in a ring around the abscess, with as few punctures through the skin surface as possible and with care taken that the injection not spread bacteria from infected to healthy tissue. At least 20 minutes should be allowed for this to take effect.

Once anesthesia has been attained, incision and drainage of an abscess involves four steps—incision, blunt dissection to disrupt loculations, irrigation, and packing. The skin is prepared with povidone-iodine, although this is a nonsterile procedure and expensive sterile gloves are not needed. A single incision across the abscess is made, but there is little evidence to guide us in determining how large to make the incision. Incisions parallel to cutaneous tension lines will leave smaller scars. A small clamp is used to probe the cavity and disrupt loculations by opening the clamp through the loculations. Blunt dissection rarely risks injury to vessels and nerves, but the initial sharp incision should be made with such structures in mind. The drained cavity can be irrigated to break loculations further, although there is no evidence to support the practice. Traditionally, the abscess is then packed and left to heal without closure. However, recent research has suggested that packing may not be beneficial, and abscesses may safely be sutured closed immediately after incision and drainage. Further study may be required before this practice becomes widespread.

Bartholin’s abscesses are drained from the mucosal rather than from the cutaneous surface. The Word catheter is a device used to keep the surgical wound from closing (Fig. 129.4) because the abscess will recur if the wound is allowed to close. A very small incision (≈3 mm) is made, and the cavity is drained. Testing for chlamydia or gonorrhea is recommended. The catheter is inserted and inflated with about 4 mL of water or saline. The catheter should be left in place for 4 to 6 weeks so that a sinus tract will have time to form. Sitz baths may help keep the area clean and draining. Antibiotics are usually not necessary but should be considered when there is extensive surrounding erythema or induration. Marsupialization is used in recurrent cases to prevent further recurrences and is usually deferred until the acute inflammation has subsided. A large incision is made, and the interior of the abscess is then sutured to the surrounding mucosa so that the abscess is sutured open.

Disposition
Self-sufficient immunocompetent patients can be discharged to home after incision and drainage of an uncomplicated superficial abscess. It is traditional to schedule one or more visits for wound checks, but many patients can remove the packing themselves after 2 to 4 days and be instructed to return for reevaluation only if there is persistent or worsening pain or other symptoms indicative of treatment failure.

IMPETIGO

Principles
Impetigo is a common superficial skin infection that is most prevalent in children aged 2 to 5 years, but it can occur at any age.

It is communicable, spread by person to person transmission, autoinoculation, and fomites. It may be manifested as an infection of previously intact skin or may infect skin that has been damaged from minor trauma or atopic dermatitis.

Impetigo rarely progresses to systemic illness. However, most cases of poststreptococcal glomerulonephritis are believed to be caused by impetigo and not pharyngitis. Its onset is usually 10 days after the onset of impetigo but may occur up to 5 weeks later.

Clinical Features and Differential Diagnosis

The two main forms of impetigo are nonbullous and bullous. Nonbullous impetigo, or impetigo contagiosa, is the most common. It was believed for many years that group A streptococci were the primary cause of this disorder, but studies have subsequently shown that most cases are due to *S. aureus*. Approximately one-third of cases have *S. pyogenes* isolated, usually in combination with *S. aureus*. The lesions begin as thin-walled vesicles that progress to pustules; subsequent rupture results in the characteristic so-called honey crusted lesions, typically found on the face or extremities. Associated lymphadenopathy is common.

Bullous impetigo is caused by *S. aureus*, including CA-MRSA. The bacteria produce an epidermolytic toxin that causes separation of the dermal-epidermal junction, resulting in bullae. The lesions in bullous impetigo are fewer and larger (0.5–3 cm) but rupture less readily than the vesicles of the nonbullous form. After rupture, the bullae leave a thin brown crust.

Ecthyma, or deep impetigo, is a less common ulcerative form of impetigo that extends through the epidermis into the dermis. It is manifested as ulcers with a punched-out appearance, with raised reddened margins covered with thick crust. It has a predilection for the lower extremities. Unlike impetigo, ecthyma can result in cutaneous scarring.

Impetigo can be confused with contact dermatitis, varicella, herpes simplex, bullous pemphigoid, and Stevens-Johnson syndrome. It does not affect mucous membranes.

**INFECTIONS OF THE PILOSEBACEOUS FOLLICLE**

**Principles**

Folliculitis, furuncles, and carbuncles are purulent infections originating in the hair follicle. They are more likely to occur after damage to the hair follicle, such as from shaving. Acne and hidradenitis suppurativa (acne inversa) result from the obstruction of sebaceous glands.

**Clinical Features and Management**

Folliculitis usually resolves on its own but can be treated with warm compresses or topical mupirocin. Multiple sites or a large cluster can warrant systemic antibiotics, although no randomized trials have been conducted on the efficacy of this treatment. Shaving of the involved area should be avoided. Hot tub folliculitis usually resolves on its own without specific treatment, effective against MRSA. Bullous impetigo should be treated with systemic antibiotics active against MRSA and streptococcus. I recommend clindamycin or cephalaxin plus trimethoprim-sulfamethoxazole.

**Management**

Nonbullous impetigo should be treated with topical mupirocin, which is active against most MRSA strains; however, extensive disease or multiple lesions should be treated with oral agents
but antihistamines and ciprofloxacin are treatment options. Fungal folliculitis is treated with topical antifungal agents. AIDS-associated folliculitis may be eosinophilic or fungal and may be treated with isotretinoin topically or systemic antifungals, respectively.

**Furuncles and Carbuncles**

A furuncle, or boil, is an infection of the hair follicle in which suppuration extends through the dermis into the subcutaneous tissue (see Fig. 129.1). Furuncles are painful and erythematous and often drain spontaneously. The most common cause is *S. aureus*, both methicillin-sensitive and CA-MRSA. Whirlpool baths at nail salons have been implicated in mycobacterial furunculosis. A carbuncle comprises multiple furuncles with loculations and connecting sinuses, often with multiple sites of drainage. Systemic symptoms may occur. Carbuncles are more likely to occur on the back of the neck and are more prevalent in diabetics.

Furuncles and carbuncles are treated in the same manner as skin abscesses, primarily with incision and drainage. There is insufficient evidence to recommend for or against antibiotics, but I suggest coverage for streptococci and MRSA when disease is severe. Small furuncles may be treated initially with a trial of warm compresses to promote drainage.

**Acne**

Acne results from the obstruction of sebaceous glands. It is most common during adolescence because of hormonal stimulation. Recommended therapies include oral doxycycline, topical clindamycin, or topical retinoids.

**Hidradenitis Suppurativa (Acne Inversa)**

Hidradenitis suppurativa (acne inversa) is an exquisitely painful condition usually seen in the axilla. It may also occur in other apocrine gland–bearing skin, including the perineum, breasts, and inner thighs. It is about three times more common in females than in males. There is some familial predisposition. The typical onset is between puberty and 40 years. It is currently believed to be an acneiform disorder that begins with follicular occlusion, rather than infection of the sweat glands. This has led to suggestions that the term *hidradenitis suppurativa*, which means suppurative inflammation of the sweat glands, be replaced with the term *acne inversa*, which implies an origin of follicular obstruction. The pathophysiologic mechanism remains incompletely understood and is likely to be a complex interaction of hormonal, environmental, and genetic factors.

The clinical course varies from intermittent isolated inflamed nodules to recurrent draining cysts and sinuses that can progress to a chronic and debilitating condition that is difficult to treat. Recurrences can lead to scarring, sinus tract formation, and disfigurement. This is a debilitating disease, and patients suffer not only from pain but also from social stigma due to the odor that may accompany the lesions and may suffer reactive depression.

The diagnosis of abscess is made on the basis of the characteristic clinical presentation. Perianal and vulvar manifestations of Crohn’s disease may be similar. Most emergency clinicians manage exacerbations with incision and drainage, although it is uncertain whether this accelerates healing. I recommend incision of painful nondraining abscesses for symptomatic relief. Systemic antibiotics are usually prescribed and should cover CA-MRSA. Perianal lesions should be treated more broadly with agents active against CA-MRSA, gram-negative organisms, and anaerobes. Amoxicillin–clavulanic acid plus trimethoprim-sulfamethoxazole is recommended.

Long-term treatment is complex and remains a subject of debate. Options include immunomodulators (eg, steroids, cyclosporine), hormones, and en bloc resection. All patients should be instructed to stop smoking and keep the area clean and dry. Pain control is essential. Patients rarely show signs of systemic illness and thus can be discharged and referred to a plastic surgeon or dermatologist.

**Necrotizing Skin and Soft Tissue Infections**

**Principals and Clinical Features**

Necrotizing infections progress rapidly, cause extensive tissue destruction, and can be fatal, despite aggressive treatment. Clinical manifestations that suggest a necrotizing infection are signs of systemic toxicity, including abnormal vital signs, severe pain or pain out of proportion to physical findings, altered mental status, rapidly advancing infection, crepitus, hemorrhage, sloughing, and blistering. Some patients appear well at presentation, and overlying skin may not be involved initially. Extensive tissue destruction occurs eventually; the mortality rate is 20%.

Risk factors include diabetes, vascular insufficiency, and immunosuppression, although healthy people are vulnerable. Inciting events include penetrating trauma, recent surgery, varicella infection, injection drug use, burns, and childbirth.

Typical bacterial isolates include group A beta-streptococci, *S. aureus*, including CA-MRSA, enterococci, Enterobacteriaceae, and the anaerobes *Bacteroides* and *Clostridium*. Most cases are polymicrobial. The classification schemes historically used for necrotizing infections are less important than the general principles discussed earlier.

Necrotizing fasciitis is an aggressive infection of subcutaneous tissues that spreads rapidly along fascial planes. In the operating room, the fasciae are inflamed, and tissue layers separate friably. It is caused by direct extension from a skin lesion in 80% of cases. Two types are described. Type I is polymicrobial, with aerobes and anaerobes; it is more common in diabetics and immunocompromised individuals. Type II is caused by a single organism, in any age group and in patients who are not chronically ill. Group A streptococci are most common; this aggressively virulent agent is known as flesh-eating bacteria. CA-MRSA is also a cause, although it appears to be less virulent. Initial symptoms may be vague (eg, malaise, fever, body aches, nausea, diarrhea). There may initially be diffuse or fusiform swelling of an extremity, or it may appear to be a simple cellulitis or wound infection. Physical findings may not be obvious initially, and pain out of proportion to physical findings is a clue. Eventually, the skin turns violaceous or ecchymotic. Anesthesia may develop over the involved tissue because of infarction of superficial nerves. Subsequent inflammation may result in the classic sign of so-called wooden-hard subcutaneous tissues.

Skin infections in the perineum warrant extra caution. *Fournier’s gangrene* is the term given to necrotizing polymicrobial infections of the perineum. Fournier’s gangrene progresses rapidly to extend to the entire perineum or abdominal wall. It can be recognized by severe pain, tenderness, and induration.

**Myonecrosis, myositis, and pyomyositis** refer to infections of muscle, which are rare. They may result from local spread of an adjacent infection, penetrating trauma, vascular insufficiency, or hematogenous spread. Clostridial myonecrosis, also known as gas gangrene, has two forms, a more common traumatic form and a rare spontaneous form. The traumatic form typically occurs from an injury that results in an interruption in the blood supply, and crush injuries are often implicated. The infection is most common due to *Clostridium perfringens*, a gram-positive spore-forming bacillus that is ubiquitous in nature, including the normal human body. Inoculation of the organism into tissue with low...
oxygen tension allows proliferation. Exotoxins destroy tissue, contribute to shock, and may cause intravascular hemolysis, with anemia and disseminated intravascular coagulation (DIC). Patients present with severe pain. The skin may initially be pale, then bronze, and eventually purplish red. Hemorrhagic bullae may develop. Soft tissue gas may not be present initially. Systemic toxicity and shock ensue when aggressive treatment is not initiated early and sometimes occurs despite aggressive treatment. The spontaneous form of clostridial myonecrosis is very rare and occurs without any inciting wound. It is usually due to Clostridium septicum and occurs in patients with bowel disease, such as colon cancer. Synergistic nonclostridial myonecrosis is a related syndrome, usually seen in the immunocompromised.

Anaerobic streptococcal myositis usually results from trauma or is a postoperative complication. It resembles clostridial myonecrosis but has a more insidious course. It is caused by anaerobic streptococci, including Peptostreptococcus, but the infection may also include group A streptococci and S. aureus.

Spontaneous gangrenous myositis—also known as spontaneous streptococcal gangrenous myositis, group A streptococcal necrotizing myositis, or streptococcal myonecrosis—is rare but aggressive and fatal in most cases. It occurs spontaneously, without trauma, in immunocompetent hosts. It is preceded by a prodromal influenza-like phase. Gangrenous necrosis of skeletal muscle then results in severe pain, with tense local swelling.

Pyomyositis is a deep abscess within striated muscle resulting from the hematogenous spread of bacteria in the setting of muscle injury. It is usually due to S. aureus, including CA-MRSA, and is more common in those who are immunocompromised. Mortality is less than 10%.13

Differential Diagnosis and Diagnostic Testing

A necrotizing infection should be considered when a patient with cellulitis presents with a rapidly progressing course or pain out of proportion to clinical findings or when the patient appears acutely ill or has tachypnea, hypotension, or tachycardia not explained by fever or dehydration. Crepitance or radiographic air is diagnostic of a necrotizing infection unless there is another explanation (eg, recent surgery).

Phlegmasia cerulea dolens is iliofemoral vein thrombosis, which can be confused with necrotizing fasciitis. Arterial insufficiency causes gangrene, and it may be difficult to determine whether infection is present in severe or chronic cases. Similarly, compartment syndrome can be confused with necrotizing infection or coexist with it.

The diagnostic gold standard is the characteristic appearance of the tissue by direct visualization in the operating room. Some surgeons may elect to perform an exploration at the bedside.

A panel of blood tests has been evaluated as a way to differentiate necrotizing infections from other skin infections, the Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) score. Points are assigned for laboratory abnormalities, and a score of 6 or more is strongly predictive of necrotizing infection, with a positive predictive value of 92% and negative predictive value of 96%. However, this tool is too preliminary for clinical applicability for several reasons, including methodologic flaws, lack of validation of the findings at other sites, uncertainty about how the score should be implemented in ill-appearing patients, and absence of any data to indicate when the score should be calculated for well-appearing patients. An even simpler decision aid relies on serum sodium concentration and white blood cell count but is similarly lacking in external validation and other criteria needed for clinical application. Necrotizing infections are very rare, and other skin infections are common. The diagnosis of necrotizing infection remains clinical, and universal laboratory screening of well-appearing patients is not recommended.

Plain radiographs may show air in the soft tissues, but absence of this finding does not rule out necrotizing infection. Ultrasound examination can visualize the abscess of pyomyositis. CT and MRI may show compelling evidence of a necrotizing infection, but their negative predictive values have not been quantified. Published studies have not supported a single approach to imaging patients at risk for necrotizing infections. The decision to begin evaluation with lower cost tests with low sensitivity versus higher cost tests with higher sensitivity will depend on a patient’s clinical status and the emergency clinician’s index of suspicion for the disorder.

Management and Disposition

Patients with suspected necrotizing infections should be resuscitated aggressively and have coagulation studies and a type and screen performed because emergent surgery may be needed. Renal function should be assessed and goal-directed therapy used to guide resuscitation.

I recommend prompt administration of broad-spectrum antimicrobials. A good regimen is clindamycin plus a broad-spectrum β-lactam such as ampicillin-sulbactam plus vancomycin to cover MRSA, in that order. Maximal doses should be used. In patients at risk for hospital-acquired infections, drug-resistant P. aeruginosa and extended-spectrum, β-lactamase–producing gram-negative bacteria should be considered.

When a necrotizing infection is suspected, a surgeon should be consulted. Repeated operative debridement is often needed. Fasciotomies are often necessary because these syndromes are associated with elevated compartment pressures, which contribute to myonecrosis. The efficacy of hyperbaric oxygen in the management of necrotizing infections is unproven, and treatment should not delay surgery.

TOXIC SHOCK SYNDROMES

Principles and Clinical Features

The main systemic, toxin-mediated, bacterial skin syndromes are staphylococcal scalded skin syndrome, streptococcal toxic shock syndrome, and staphylococcal toxic shock syndrome. These are caused by bacterial exotoxins known as superantigens because they cause a severe and pathologic host immune system response by stimulating T lymphocyte activation and functioning as mitogens in vitro. Systemic disease results from the immune system’s response to the toxin, but may be accompanied by or simply resemble bacteremic septic shock (Table 129.3).

Streptococcal Toxic Shock Syndrome

Streptococcal toxic shock syndrome (TSS) is a severe, toxin-mediated syndrome that rapidly progresses to shock, with multiorgan failure and death. Identified in the mid-1980s, this syndrome is caused by group A streptococci, often in the setting of a severe soft tissue infection. Most victims were previously healthy. The syndrome is a rare sequel of disseminated varicella (chickenpox).

Invasive group A streptococcal infections are often due to M-type isolates with potent exotoxins. Signs and symptoms are caused by pyrogenic exotoxins A and B. These act as superantigens and cause overactivation of T cells with a massive release of cytokines, including interleukins and tumor necrosis factor.

Patients may have an influenza-like prodrome with nausea, vomiting, diarrhea, myalgias, and chills. High fever, hypotension, and tachycardia are typical. Altered mental status with confusion is common. A diffuse rash is present in 10% of cases, which may make differentiation from staphylococcal TSS more difficult.
On presentation, the patient has a severe streptococcal infection; necrotizing fascitis is present in 50% of cases. Pain is often out of proportion to physical findings. Most patients present with shock or develop it within 4 to 6 hours. Bacteremia is common, with positive blood cultures in about 60% of cases. Serious multisystem complications are common, including DIC, acute renal failure, and acute respiratory distress syndrome. In contrast to staphylococcal TSS, which is infrequently fatal, about 30% to 80% of patients diagnosed with streptococcal TSS die. Epidermolysis, typical of staphylococcal TSS, is not characteristic of the streptococcal variety.

**Staphylococcal Toxic Shock Syndrome**

Although staphylococcal TSS is not as severe as the streptococcal variety, it remains a life-threatening systemic illness. The classic presentation is of fever, rash, and hypotension, often in patients who were previously healthy. It was first described in 1978 and, beginning in 1980, there was an epidemic of cases associated with the use of highly absorbent tampons. Menses-associated cases have since declined dramatically when these tampons were eliminated from the market, although tampon use continues to remain a risk factor.

Nonmenstrual cases, which currently account for about 50% of cases, are associated with a variety of conditions, including surgical procedures (eg, rhinoplasty, abortion), nasal packing, burns, injection drug use, and the postpartum state. To the emergency clinician, menstrual and nonmenstrual staphylococcal TSS appear similar, and the source infection is often not readily apparent. Of note, prevention of TSS was a traditional indication for systemic antibiotic therapy after nasal packing for epistaxis, but recent evidence has suggested that this is not necessary, and topical antibiotics may be a preferred approach.

*S. aureus* exotoxins are superantigens that are able to activate large numbers of T lymphocytes, resulting in the massive release of inflammatory mediators, including interleukins, tumor necrosis factors, and interferon. Toxic shock syndrome toxin 1 (TSST-1) is associated with most menstrual cases. A lack of antibody against this toxin has been demonstrated in patients with menstrual staphylococcal TSS. Episodes of recurrent staphylococcal TSS have been reported in patients who do not mount a long-term antibody response, and it has been postulated that the toxin may interfere with antibody generation against itself.

Patients often have an acute onset of fever, chills, malaise, myalgia, muscle tenderness, and diffuse blanching macular rash that is not puritic. There may be nausea, vomiting, or diarrhea. Patients may have altered mental status. Vital signs usually indicate fever and low blood pressure.

Severe hypotension may ensue as a result of massive vasodilation and fluid shifts out of the intravascular space. Toxic cardiomyopathy may also contribute to the low blood pressure. Hypotension or rhabdomyolysis may cause acute tubular necrosis. Anemia, thrombocytopenia, and leukocytosis are common, and DIC may develop. Desquamation of the skin, including the palms and soles, eventually occurs 7 to 14 days after onset. The overall mortality is below 5% with aggressive supportive care.

**Staphylococcal Scalded Skin Syndrome**

Staphylococcal scalded skin syndrome (SSSS) is a desquamating skin disorder caused by exfoliating toxins produced by *S. aureus*. SSSS was historically known as fourth disease and in newborns as Ritter’s disease. A disease of infants, it is rare in older children and adults. It can cause outbreaks in nurseries and daycare centers.

SSSS is caused by certain strains of *S. aureus*, including CA-MRSA, that produce epidermolytic toxin A or epidermolytic toxin B. These toxins probably act as proteases that target the protein desmoglein 1 on the stratum granulosum layer of the epidermis. Whether they meet the T lymphocyte mitogenic criterion for a superantigen has been a subject of debate, and this may be relevant to the prognosis, which is good relative to TSS.

The severity of the disease ranges from a few blisters at the site of infection to exfoliation of most of the body. People with preexisting toxin antibodies develop the localized form, in which toxin is found in the wound periphery; those without preexisting toxin antibodies develop the generalized form, in which toxin spreads through the bloodstream. Cultures of the bullae are negative unless they are contaminated or secondarily infected.

Typically, a young child presents with fever, irritability, and tender red rash. The erythema progresses to bullae formation and subsequent exfoliation of the affected skin. The skin exhibits

Nikolsky’s sign, which is separation of the epidermal layer of skin on gentle stroking. Desquamation may be patchy or sheeplike, leaving the skin denuded, with a red moist base and predisposing it to secondary infection. Perioral, perianal, and flexural skin may be affected more severely. Mucous membranes are spared. SSSS is not associated with multisystem illness and typically does not lead to shock. Mortality is 1% to 5% and is usually a result of complications from comorbid conditions or superimposed infection.

Early SSSS may be difficult to differentiate from bullous impetigo. The lack of mucosal involvement helps differentiate SSSS from toxic epidermal necrolysis and Stevens-Johnson syndrome. Other differential considerations include Kawasaki syndrome, Rocky Mountain spotted fever, meningococcemia, leptospirosis, and heat stroke.

**Differential Diagnosis and Diagnostic Testing**

Streptococcal TSS should be suspected in any patient presenting with shock, especially if the patient was previously healthy. Diagnostic criteria for streptococcal TSS include the presence of group A streptococcal infection, hypotension, and two of the following: renal impairment, liver abnormalities, acute respiratory distress syndrome, coagulopathy, necrotic soft tissue infection, and rash. These criteria were developed for epidemiologic purposes; failure to meet all criteria should not exclude the clinical diagnosis in suspicious cases.

Staphylococcal TSS should be considered in any patient presenting with diffuse rash and hypotension. The diagnosis is made on the basis of the clinical presentation. The characteristic rash often raises suspicion and ultimately aids in establishment of the diagnosis. Isolation of *S. aureus* is not necessary for the diagnosis to be made; in fact, blood cultures are positive in a small minority of cases. In severe cases, laboratory abnormalities are those resulting from shock and organ damage.

**Management**

Streptococcal and staphylococcal TSS require critical care resuscitation. In streptococcal TSS, immediate surgical consultation for operative débridement of necrotizing infections is critical. In staphylococcal TSS, any potential source of infection should be removed, such as tampons or wound packing, and all postoperative wounds should be explored for infection.

Clindamycin and vancomycin should be administered. Gram-negative coverage should be added when the diagnosis of TSS is uncertain because the clinical picture overlaps with that of septic shock.

IV immune globulin has theoretic benefit, but its efficacy has not been shown in clinical trials. It is a reasonable option in cases of presumed staphylococcal TSS unresponsive to IV fluids and vasopressors, but this is not standard in the ED setting. There has been conflicting evidence on its efficacy for the treatment of streptococcal TSS. SSSS is treated with antibiotics active against *S. aureus*, including MRSA. Wound care and hydration are important.

**Disposition**

Patients with suspected TSS should be admitted, usually to the intensive care unit, for IV fluids, antibiotics, and close monitoring due to the potential for decompensation. Patients with necrotizing soft tissue infections associated with streptococcal TSS usually require surgical débridement.

Children with mild SSSS may be considered for outpatient management with oral antibiotics and close follow-up. Those with more severe skin involvement often need admission for pain control as well as for temperature regulation and fluid and electrolyte management. Severely affected patients may need intensive or burn center care. With proper supportive care and antibiotic treatment, the prognosis is excellent, with an overall mortality of less than 5%. Scarring is rarely severe.

**OTHER INFECTIONS WITH SKIN MANIFESTATIONS**

*Borrelia burgdorferi* is the spirochete that causes Lyme disease, endemic in the United States, especially in New England. It produces a characteristic targetoid rash known as erythema migrans, which emerges about 1 month after the infecting tick bite. The targetoid appearance results from central clearing of the erythema. However, 20% of Lyme disease patients do not report a rash, and the rash does not always have the characteristic round and targetoid appearance (see Chapter 126).

Another spirochete, *Treponema pallidum* (syphilis), is an increasingly rare cause of rash. The primary lesion of syphilis is a painless ulcer at the inoculation site, known as a chancre, with raised borders and regional lymphadenopathy. The chancre appears days to months after infection and resolves in approximately 1 month. Secondary syphilis develops weeks to months later in about 25% of infected patients. It involves a rash that can take any form other than vesicular and includes the palms and soles; there is usually diffuse lymphadenopathy. Syphilis is uncommon in the United States, although about 10,000 cases still occur annually (see Chapter 88).

Rocky Mountain spotted fever, caused by *Rickettsia rickettsii*, is even more uncommon, diagnosed only about 2000 times each year in the United States. A few days after a bite by a dog tick or wood tick, the characteristic rash begins on the wrists and spreads everywhere, including the palms and soles. It starts macular and becomes petechial and then dusky. Of those infected, 10% never develop a rash. The untreated mortality for Rocky Mountain spotted fever approaches 25%, but treated patients do well.

Cutaneous anthrax is transmitted from animal products of infected animals, such as wool or pelts, to exposed areas of veterinarians and farmers. A spore of the gram-positive anaerobe *Bacillus anthracis* enters a break in the skin and, after an incubation period of about 1 week, a vesicle forms. This ruptures, leaving a shallow-based ulcer with a raised border. The lesion progresses to painless necrosis and the characteristic eschar. Severe surrounding edema is due to bacterial toxins. The lesions may be confused with recluse spider bites. Unlike the case with inhalational anthrax, treated cases do well, and even untreated cases have a mortality rate of less than 20%.

Tularemia is a rare disease resulting from exposure to animals such as rodents, rabbits, and hares and is endemic in much of the United States, especially the south central states. The ulceroglandular form is most common and involves an influenza-like illness with a single raised ulcer that has a mild central eschar formation. The lesion itself is raised, rather than the border, which might suggest anthrax (see Chapter 126).

The floor of the mouth is a dangerous location for soft tissue infections. Severe infections may progress to Ludwig’s angina, in which the floor of the mouth becomes severely indurated. Ludwig’s can be fatal due to airway obstruction. Broad-spectrum antibiotics are indicated. Steroids may reduce swelling. Intubation should be considered and a difficult airway anticipated (see Chapter 65).

Scabies is a skin infestation of the parasitic mite *Sarcoptes scabiei*. It is endemic worldwide and can cause institutional outbreaks. Lesions are most prominent on the dorsal aspect of the hand and in intertriginous areas. It is diagnosed by visualization of characteristic burrows and, in ambiguous cases, by microscopy of skin scrapings. It is treated with topical permethrin or a single dose of oral ivermectin (200 µg/kg). Norwegian scabies, also
known as crusted scabies, is an aggressive infestation that occurs in the immunocompromised; it is treated with permethrin and ivermectin (see Chapter 110).

Cat-scratch disease results from Bartonella henselae infection after a cat bite or scratch. Its hallmark is regional lymphadenopathy that appears weeks after a primary lesion at the site of inoculation. Treatment is with a standard 5-day course of azithromycin, with a double dose on day 1.

Strongyloidiasis is caused by infection with the parasitic helminth Strongyloides stercoralis. Skin lesions can appear years after infection and are urticarial or serpiginous. A rapidly extending burrow that is pruritic and erythematous is diagnostic; this finding, due to rapid migration of larvae in the skin, is known as larva currens (running larva). Such findings or unexplained eosinophilia in people who have lived in Southeast Asia or tropical Africa should prompt consideration of strongyloidiasis. Diagnosis is by an enzyme-linked immunosorbent assay performed on serum. Detection is important because, unlike other nematodes, strongyloides can complete its life cycle in the human host, leading to lifelong infection. When the infected patient becomes immunosuppressed by medications or illness, the strongyloides hyperinfection syndrome can result and is often fatal (see Chapter 125).

Cutaneous larva migrans is another serpiginous skin lesion caused by migrating larvae. In this case, the organism is hookworm, and the site is typically the foot or buttock; it is often seen after a vacation on the beach in Mexico. Treatment is with a single dose of ivermectin 200 mg/kg (see Chapter 125).

Cutaneous leishmaniasis is common in many parts of the world and is found on every continent except Australia and Antarctica. It is caused by protozoans of the genus Leishmania and is transmitted by sandflies. Lesions are most common on the face and are painless, ulcerative, and disfiguring. Papules in returning travelers and immigrants should raise suspicion of myiasis (botfly) and, rarely, dracunculiasis (Guinea worm).

**KEY CONCEPTS**

- Skin infections are common and are rarely life-threatening. Deadly necrotizing skin and soft tissue infections are rare, and there is insufficient evidence to motivate screening by laboratory tests.
- Necrotizing infection is suggested by pain out of proportion to physical findings, crepitance, gas seen on imaging studies, or clinical instability. Suspected necrotizing infection is managed aggressively, with broad-spectrum antibiotics, critical care resuscitation, and surgical consultation.
- Emergency clinicians should be familiar with toxic shock syndromes and Rocky Mountain spotted fever, which are rare, life-threatening, skin infection–related syndromes. Lyme disease should be considered in endemic areas.
- For the management of most skin abscesses, antibiotics are not recommended. Adequate analgesia or sedation are essential to good patient care. There is debate about the necessity of wound culture and Gram staining.
- Current recommendations for the treatment of cellulitis suggest agents effective against streptococci and methicillin-sensitive Staphylococcus aureus (eg, cephalaxin at maximal doses). Adjunctive measures are essential to a good treatment response— NSAIDs, immobilization, elevation, and compression.
- Clindamycin monotherapy is an excellent choice for the treatment of skin infections because it covers streptococci and most staphylococci, including most CA-MRSA isolates.
- Although they are active against CA-MRSA, trimethoprim-sulfamethoxazole and tetracyclines may not be effective for streptococci and are not recommended for cellulitis monotherapy.
- There is insufficient evidence to recommend measurement of the white blood cell count in patients with skin infections.
- Blood cultures are not necessary for the evaluation of skin infections, except with septic shock, necrotizing infections, immunocompromise, multifocal infections suggesting hematogenous seeding, infections complicating lymphedema, and perhaps facial cellulitis.
- Skin infection mimics include venous stasis dermatitis and other forms of dermatitis.

CHAPTER 129: QUESTIONS & ANSWERS

129.1. Which of the following statements regarding cellulitis is true?
   A. Bilateral cellulitis of the lower extremities is a common bacterial infection.
   B. Computed tomography (CT) can rule out necrotizing fasciitis.
   C. Fever and leukocytosis are key to the diagnosis.
   D. Needle aspiration of the leading edge is unlikely to identify the causative organism.
   E. Ultrasound evaluation cannot rule out a large abscess.

   Answer: D. Needle aspiration and even biopsy are rarely able to identify a causative organism in nonpurulent cellulitis. Fever and leukocytosis are often absent, and measurement of the white blood cell count is not indicated. Ultrasound evaluation is sensitive and specific and can rule out a large abscess, although distinguishing small abscesses from the cobbledstoning of cellulitis can be difficult. Bilateral lower extremity inflammation is usually venous stasis dermatitis, which can be confused with cellulitis. Bilateral cellulitis is rare and suggests hematogenous dissemination.

129.2. A 7-year-old girl presents with right periorbital pain and swelling. Physical examination reveals a temperature of 38° C (100.4°F), periorbital edema, erythema, and warmth. Some erythema and edema of the eyelids occur as well. Vision, extraocular movements, and pupils are normal. Which of the following statements regarding this patient's condition is true?
   A. An urgent CT scan is indicated.
   B. Plain radiographs of the sinuses are indicated.
   C. Progression to the other eye is likely.
   D. Progression to vision loss is likely.
   E. She should be treated as an outpatient with antibiotics targeting staphylococci.

   Answer: E. Well-appearing children with no eye pain or pain on extraocular movement may be diagnosed with preseptal cellulitis and treated as outpatients if the parents can be trusted to return for failure to improve. Historically, Haemophilus influenzae type B was an important organism but, in vaccinated children, this is less likely; unvaccinated children should receive an agent effective against this organism. Orbital cellulitis is suggested by change in vision, eye pain, pain with extraocular movements, or a toxic appearance. When there is doubt, CT scanning is appropriate but not mandatory in all cases. Most cases are unilateral. Progression to endophthalmitis and vision loss is not expected with preseptal cellulitis, although it can occur in orbital cellulitis.

129.3. A 53-year-old woman presents with fever and painful swelling of the left side of her face. The physical examination is remarkable for a toxic-appearing woman with a sharply demarcated, raised, bright red, and extremely tender eruption involving the left side of her face. Which of the following statements regarding this patient's condition is true?
   A. Echocardiography is indicated.
   B. Fluoroquinolones are first-line antibiotics.
   C. Penicillin G monotherapy is the correct treatment.
   D. The face is the most commonly involved site.
   E. There is an association with glomerulonephritis.

   Answer: E. Erysipelas is an acute cellulitis typically caused by group A streptococci. It presents with an angry red area of inflammation that is well-demarcated from the surrounding skin and has a raised border. Like other group A streptococcal skin infections, erysipelas can give rise to poststreptococcal glomerulonephritis. Penicillin G is probably the ideal therapy, but any toxic-appearing patient should be treated more aggressively, with goal-directed therapy and broad-spectrum antibiotic coverage. H. influenzae is a classic cause of facial cellulitis but is more common in children, is rare in the era of Hib vaccination, and typically causes transdermal cellulitis, rather than the more superficial form of cellulitis known as erysipelas. The lower extremities are usually involved.

129.4. A 5-month-old girl presents with fever and a diffuse dermatitis characterized by bulla formation, with surrounding vesicles leading to the loss of large sheets of epidermis. She has no past medical history and has been on no medications. The areas of desquamation are tender and red. Which of the following statements regarding this patient's condition is true?
   A. Antibiotics are not indicated.
   B. Corticosteroids will help prevent progression.
   C. Culture of the bullae is not indicated.
   D. Mortality is greater than 30%.
   E. Mucous membranes are likely affected.

   Answer: C. Staphylococcal scalded skin syndrome is a toxin-mediated process occurring in the very young (6 months–6 years) and older adults. The cornerstone of treatment is hydration and
antistaphylococcal antibiotics. Culture of bulla fluid is generally negative. Mucous membranes are spared. This condition is rarely fatal.

129.5. A 7-year-old boy presents with a left leg rash. The mother describes an initial sequence of a patch of small red papules that rapidly became vesicular, then pustular, and then crusted over. You observe a 2- × 3-cm area on the left thigh, with heavily crusted erythematous macules. There is moderate left inguinal lymphadenopathy. The lesions are not tender, and the child is not toxic-appearing. Which of the following statements regarding this patient’s condition is true?

A. Acute rheumatic fever is a risk.
B. Corticosteroids are indicated.
C. Systemic antibiotics are necessary.
D. The streptozyme test is highly reliable.
E. Topical mupirocin is indicated.

Answer: E. Impetigo involves a blistering eruption with a honey-colored crust. It may be caused by streptococci or staphylococci. For limited disease, topical mupirocin is the treatment of choice. Oral or systemic antibiotics are only indicated for more severe cases. Corticosteroids are not indicated. No laboratory test is useful. Acute rheumatic fever does not occur after impetigo. Poststreptococcal glomerulonephritis may occur, but is less likely than after pharyngitis.

129.6. Which of the following statements about skin infections in the age of community-associated methicillin-resistant Staphylococcus aureus (CA-MRSA) is false?

A. CA-MRSA is usually associated with mild disease.
B. Evidence is lacking that CA-MRSA plays a role in nonpurulent skin infections.
C. The cause of most cases of cellulitis is unknown.
D. Abscesses should be treated with antibiotics active against CA-MRSA.
E. The streptozyme test is highly reliable.

Answer: E. Multiple trials have suggested that antibiotics are not beneficial when an abscess is treated with incision and drainage. Only extraordinarily large abscesses, multiple abscesses, and other special cases merit antibiotic treatment. When antibiotics are used, they should cover CA-MRSA. Most cases of CA-MRSA disease are mild, purulent, skin infections. So far, no clinical trial has demonstrated benefit of trimethoprim-sulfamethoxazole for the treatment of any skin infection. The cause of nonpurulent cellulitis is usually impossible to ascertain because even biopsy rarely yields a positive culture. There is insufficient evidence that CA-MRSA is an important pathogen in nonpurulent cellulitis to justify the use of anti-CA-MRSA antibiotics in its treatment.

129.7. A young woman presents complaining of a painful itchy rash. She has just returned from a vacation in the Caribbean, where she was snorkeling. Examination reveals streaks of erythema with slight vesiculation along the lateral aspect of the right leg. The lesions are oriented diagonally, not along vascular lines, and are about 15 cm long. What is the most appropriate next step in this patient’s management?

A. Obtain a CT scan to assess for necrotizing fasciitis.
B. Perform a Tzanck smear performed on an unroofed vesicle.
C. Treat with acyclovir.
D. Treat with corticosteroids.
E. Treat with trimethoprim-sulfamethoxazole.

Answer: D. This is an example of contact dermatitis, likely from seaweed or jellyfish stings. Nothing in the presentation is suggestive of an infection. Trimethoprim-sulfamethoxazole monotherapy is rarely appropriate because abscesses generally do not require antibiotics, and streptococci are thought to be covered poorly by this antibiotic. A Tzanck smear and acyclovir treatment would be appropriate if herpetic infection were suspected, but neither herpes simplex nor varicella zoster would present with 15-cm streaks.
Sepsis Syndromes

Nathan I. Shapiro  |  Alan E. Jones

**PRINCIPLES**

**Background**

Sepsis syndrome represents the body’s host response to an infection. The causative agent and host’s activated inflammatory cascade overwhelm the body’s defenses and regulatory systems, leading to disruption in homeostasis. Tachycardia, tachypnea, fever, and immune system activation are common manifestations. If the body is unable to overcome this insult, cellular injury, tissue damage, shock, multiorgan failure, or death may ensue.

In 1992, the American College of Chest Physicians and Society of Critical Care Medicine issued a consensus statement to establish uniform criteria defining the sepsis syndromes. The goal was to create a common nomenclature for disease classification and systematic comparisons across studies of septic patients. The term **systemic inflammatory response syndrome** (SIRS) is defined as two or more of the following: tachycardia, tachypnea, hyperthermia or hypothermia, high or low white blood cell count, or bandemia. Sepsis is the combination of infection plus SIRS, severe sepsis is sepsis plus organ dysfunction, and septic shock is sepsis plus hypotension, defined as a systolic blood pressure below 90 mm Hg, not responsive to a fluid challenge (Box 130.1). This nomenclature is intended to provide clinicians and researchers with a common classification. Efforts to validate this classification scheme in the emergency department (ED) population have demonstrated that the term sepsis, when characterized by fulfilling the SIRS criteria alone, is overly sensitive and nonspecific and does not convey an increased mortality risk. SIRS is not specific because it can be present in noninfectious inflammatory states and in localized infections that are not inclined to lead to sepsis, such as streptococcal pharyngitis or viral illnesses. However, organ dysfunction and shock have been shown to portend worse outcomes. Newer efforts have proposed the PIRO approach, which may help us better understand and prognosticate the severity of illness. PIRO stands for assessment of predisposing conditions, infection source, response of the host, and organ dysfunction and has been proposed to help improve classification.

Bacteremia may be present, but positive cultures are not obligatory in the diagnosis of sepsis. Culture-negative and culture-positive septic populations have similar outcomes in patients with similar severity of illness. Pneumonia, abdominal abscess with vescic perforation, and pyelonephritis are common primary causes of sepsis. Gram-positive organisms account for 25% to 50% of infections, gram-negative organisms for 30% to 60%, and fungi for 2% to 10%. The distribution varies with the study and, more importantly, with host factors such as the status of the host immune system, age of the patient, recent hospitalizations, and presence of indwelling vascular catheters.

The health status of the host is a potentially important risk factor in the development and progression of sepsis. Older adults and those with multiple comorbidities may be more susceptible to developing a systemic infection. Chemotherapy-induced neutropenia, acquired immunodeficiency syndrome, and steroid dependency increase susceptibility to sepsis. Increased use of indwelling devices such as intravascular catheters, prosthetic devices, and endotracheal tubes also contribute to the risk of systemic infection and sepsis.

**Pathophysiology**

Sepsis results from the complex interaction of detection molecules, signaling molecules, and numerous inflammatory and coagulation mediators in response to infection. Although our understanding of the pathophysiologic process of sepsis has evolved, it remains incomplete. The initial host response is to mobilize inflammatory cells, particularly neutrophils and macrophages, to the site of infection. These inflammatory cells then release circulating molecules, including cytokines, which trigger a cascade of other inflammatory mediators that result in a coordinated host response. Synthesis of the components of the cascade is increased at many steps along the pathway. If these mediators are not appropriately regulated, sepsis will occur. In the setting of ongoing toxin release, a persistent inflammatory response occurs, with ongoing mediator activation, cellular hypoxia, tissue injury, shock, multiorgan failure, and potentially death.

**Mediators of Sepsis**

Host response and pathogen characteristics are both important in the pathogenesis of sepsis. More than 100 discrete markers have been identified and attributed to the sepsis cascade, but the true culprits have not been clearly identified. A pathogen is sensed by pattern recognition receptors, most notably Toll-like receptors, located on the surface of the white blood cell. The resulting host-pathogen interaction activates the inflammatory and coagulation cascades. The subsequent inflammatory signaling occurs through cytokines, chemokines, and other soluble mediators, including increased circulating levels of the interleukins IL-1, IL-6, and IL-8 and tumor necrosis factor alpha (TNF-α). Activation of the clotting cascade may result in increased D-dimer levels and decreased circulating levels of protein C.

In benign conditions, a self-limited response helps clear the pathogen. If the innate immune response is inadequate, mediators create a procoagulant state. Coagulation and fibrinolytic components are proinflammatory, precipitating a worsening cycle of procoagulant and proinflammatory mediators. Propagation of this cascade ultimately contributes to end-organ damage and often to disseminated intravascular coagulation (DIC). If it is not effectively reversed, the process leads to cellular hypoxia, organ dysfunction, shock, and death.

The primary mediators are cytokines that are primarily proinflammatory, antiinflammatory, or growth-promoting. The molecular mechanisms whereby they are regulated are not well understood. An initial cytokine, TNF-α, is found in serum approximately 90 minutes after the administration of endotoxin to healthy volunteers. IL-6 and IL-8 reach peak levels at approximately 120 minutes. The main proinflammatory cytokines include IL-1, TNF-α, and IL-8. The primary antiinflammatory cytokines are IL-10, IL-6, transforming growth factor-β, soluble receptors to
BOX 130.1

Definitions of Sepsis

- Bacteremia (fungemia)—presence of viable bacteria (fungi) in the blood, as evidenced by positive blood cultures
- Systemic inflammatory response syndrome (SIRS)—at least two of the following conditions: oral temperature > 38°C (100.4°F) or < 35°C (95°F); respiratory rate > 20 breaths/min or partial pressure of arterial carbon dioxide (PaCO₂) < 32 mm Hg; heart rate > 90 beats/min; leukocyte count > 12,000/dl or < 4000/dl; or >10% bands
- Sepsis—systemic inflammatory response syndrome (SIRS) that has a proven or suspected microbial source
- Septic shock—sepsis with hypotension that is unresponsive to fluid resuscitation plus organ dysfunction or perfusion abnormalities, as listed for severe sepsis
- Multiple organ dysfunction syndrome (MODS)—dysfunction of more than one organ, requiring intervention homeostasis

TNF, and IL-1 receptor antagonist (IL-1RA). If the resultant inflammatory response is adequate, the infection is controlled and cleared. If the response is deficient or excessive, however, a persistent and worsening cascade is produced, ultimately leading to (once again) shock, organ failure, and potentially death.

Instability in vascular tone has become increasingly important in understanding the pathophysiologic mechanism of sepsis. Vasopressin, also known as antiidiuretic hormone, is a naturally occurring hormone that is essential for cardiovascular stability. It is produced as a prohormone in the hypothalamus. The hormone is stored in the pituitary gland and released in response to stressors such as pain, hypoxia, hypovolemia, and hyperosmolality. In severe sepsis, there is a brief rise in circulating vasopressin levels followed by a prolonged and severe suppression. This pattern of secretion is different from other forms of shock, in which vasopressin levels remain elevated. Vasopressin has numerous physiologic effects, including vasconstriction of the systemic vasculature, osmoregulation, and maintenance of normovolemia.

Nitric oxide (NO) is a gas that has an important role in septic shock, regulating vascular tone by an indirect effect on smooth muscle cells. NO also contributes to platelet adhesion, insulin secretion, neurotransmission, tissue injury, and inflammation and cytotoxicity. Its half-life is short (6–10 seconds), and it easily diffuses into cells. Although its mechanisms of action are not well understood, it seems to be a key mediator of sepsis. Animal data have shown that nitric oxide synthase, the enzyme that produces NO, is upregulated in cases of sepsis. Enhanced NO production is thought to contribute to the profound vasodilation found in patients in septic shock.

In the setting of ongoing inflammatory activation, the mediators of sepsis continue to be produced, and the cascade is perpetuated. Unless it is appropriately and rapidly controlled, the ultimate effect is a sequence of events starting with cellular dysfunction and ultimately leading to tissue damage, organ dysfunction, and death.

Organ System Dysfunction

The organ dysfunction that results from sepsis is central to the pathogenesis of the disease. The mortality of patients with sepsis increases as the number of failing organs increases (Fig. 130.1A).

In one large study, the mortality rate was 1% for sepsis patients with no organ dysfunction, whereas the rates for patients with dysfunction of a single organ, two organs, three organs, and four or more organs were 6%, 13%, 26%, and 53%, respectively (see Fig. 130.1B).

Neurologic Impairment. Patients with sepsis may display neurologic impairment manifested by altered mental status and lethargy, commonly referred to as septic encephalopathy. The incidence has been reported as between 10% and 70%. The mortality rate in patients with septic encephalopathy is higher than that in septic patients without significant neurologic involvement. Although the pathophysiologic process has not been clearly defined, contributing factors may include direct bacterial invasion, endotoxemia, altered cerebral perfusion or metabolism, metabolic derangements, multiorgan system failure, and iatrogenic injury. In addition, impaired renal or hepatic function in the absence of overt organ failure has been shown to correlate with encephalopathy.

Cardiovascular Dysfunction. Cardiovascular dysfunction is common with sepsis. The cardiovascular dysfunction and failure arise from direct myocardial depression and distributive shock. Gram-negative, gram-positive, and killed organisms can cause myocardial depression. The direct insults of the toxic mediators as well as the mobilization of host mediators of sepsis produce a distributive shock. Early in sepsis, a hyperdynamic state develops, characterized by increased cardiac output and decreased systemic vascular resistance. Although the cardiac output is increased, it is at the expense of ventricular dilation and decreased ejection fraction (EF). Vigorous fluid resuscitation usually increases preload and, secondarily, EF, thereby improving

Fig. 130.1. Mortality rates by sepsis syndrome (A) and number of organ dysfunctions (B). SIRS, Systemic inflammatory response syndrome.
the cardiac index, even late in shock. Much of the cardiovascular compromise from septic shock is reversible, and normal cardiovascular function usually returns within 10 days.

**Pulmonary Involvement.** Involvement of the lung is often seen in the inflammatory response to infection. These effects are apparent, irrespective of the primary infection that caused sepsis. Early infiltration with neutrophils, surfactant dysfunction, and edema give way to monocyte infiltration and fibrosis. Significant right-to-left shunting, arterial hypoxemia, and intractable hypoxemia occur. The resulting morbidity is high and is a common endpoint to sepsis-related deaths.

Sepsis produces a highly catabolic state and places significant demands on the respiratory system. At the same time, airway resistance is increased, and muscle function is impaired. Irrespective of whether pneumonia is the cause of sepsis, the common pulmonary endpoint is acute respiratory distress syndrome (ARDS). ARDS is defined clinically and correlates with the pathologic finding of diffuse alveolar damage. The development of ARDS occurs hours to days after radiographic abnormalities develop. Because of alveolar-capillary membrane damage, fluid accumulates in the alveoli. Rather than being a diffuse disease, ARDS is a heterogeneous process that results in interspersed damaged and normal alveoli.

**Gastrointestinal Effects.** A shock state causes significant deleterious effects on a hollow viscus and its oxygen supply. A prolonged ileus accompanies hypoperfusion and persists beyond the perfusion deficit. Splanchnic blood flow is dependent on mean arterial pressure because there is relatively little autoregulation. Therefore, hemodynamic dysfunction may have a profound effect on viscus metabolism.

Solid organ involvement is also common. Even in the previously normal host, elevations in aminotransferases and bilirubin levels are common early in sepsis. The liver has also been implicated in the pathogenesis of sepsis; some of the mediators of sepsis are produced by the liver.

**Endocrine Disorders.** An absolute or relative adrenal insufficiency is common in sepsis. Depending on the balance of circulating cytokines, augmentation or suppression of the hypothalamic-pituitary axis is possible. IL-1 and IL-6 both activate the hypothalamic-pituitary-adrenal axis. TNF-α and corticotocin depress pituitary function. Other factors that may contribute to adrenal insufficiency in sepsis include decreased blood flow to the adrenal cortex, decreased pituitary function, and decreased pituitary secretion of adrenocorticotropic hormone due to severe stress. As a result of these interactions, the hypothalamic thermoregulatory mechanism may be reset, and temperature fluctuations may develop.

**Hematologic Abnormalities.** Sepsis causes abnormalities in many parts of the coagulation system. Endotoxin, TNF-α, and IL-1 are the key mediators. Pathologic activation of the extrinsic (tissue factor–dependent) pathway, protein C, protein S, and fibrinolysis lead to consumption of essential coagulation factors, causing DIC. The activation of the coagulation cascade produces fibrin deposition and microvascular thrombi. If these depositions are not corrected, they can compromise organ perfusion and contribute to organ failure. Tissue factor expression on monocytes is increased. This results in fibrin deposition and perhaps contributes to an increased incidence of multiorgan failure due to microvascular thrombi.

Protein C has been identified as an important modulator of inflammation and coagulation in patients with sepsis. Impairment of the protein C–dependent anticoagulation pathway is critical to the development of the thrombotic complications of sepsis. In healthy peoples, protein C is activated by a combination of thrombin and thrombomodulin. The activation of protein C results in the downregulation of many portions of the coagulation cascade, including release of tissue factor, inactivation of factors VIIIa and Va, and stimulation of fibrinolysis. It is possible that protein C activation in early sepsis is impaired because of an inflammatory cytokine–mediated downregulation of thrombomodulin. As a result, a consumptive coagulopathy ensues. This leads to increased fibrin deposition and a resulting upregulation of the fibrinolytic pathway, as identified by low plasma levels of the fibrinolytic proteins and increased fibrin split products. This sequence of events leads to consumption of coagulation factors and DIC. In late sepsis, the fibrinolytic system is suppressed.

**Genetic Factors**

There has been increasing evidence that genetics are a risk factor for the outcome of sepsis. An individual may contain a set of individual characteristics or polymorphisms that may affect the ways in which he or she responds to sepsis in general, or perhaps there may be differences in response to specific sepsis therapeutics. Identifying and understanding these differences in an individual’s genetic makeup is likely to lead to tailored approaches to diagnosis and therapy. The impact of genetics on future treatment modalities for sepsis remains unclear, but the prospect of customized genetic therapy for sepsis is a promising early development.

**CLINICAL FEATURES**

**Symptoms and Signs**

The approach to a patient with sepsis relies on identification of the presence of a systemic infection and localization of the source of the initial infection. This allows appropriate treatment directed to the source of infection. Often, the source is not readily apparent, but early identification of the septic state allows implementation of broad-spectrum antibiotics.

The septic patient may manifest signs of systemic infection through tachycardia, tachypnea, hyperthermia or hypothermia, and, if severe, hypotension. A septic patient will often have flushed skin with warm, well-perfused extremities secondary to the early vasodilation and hyperdynamic state. Alternatively, the severely hypoperfused patient with an advanced shock state may appear cyanotic. Very early in the patient’s presentation, vital sign changes such as tachycardia and tachypnea may be first indicators of sepsis. If the patient is in shock, a rapid assessment that excludes other causes, such as hypovolemic or cardiogenic shock, is essential to the proper initial treatment. A complete detailed clinical examination will help the emergency clinician determine the cause of the shock state (see Chapter 6). These are classic signs; however, these findings may not be manifested in a septic patient, and signs and symptoms may be subtle or absent.

Both underlying comorbidities and the cause of sepsis should be considered. Risk factors such as immunocompromised states (eg, acquired immunodeficiency syndrome, malignan disease, diabetes, splenectomy, concurrent chemotherapy), older age, debilitation, high-risk environments for iatrogenic infections (eg, acute care hospitalizations, long-term care facilities), and multiple comorbidities should be considered.

The respiratory system is the most common source of infection in the septic patient. A history of a productive cough, fevers, chills, upper respiratory symptoms, and throat and ear pain should be sought. Physical examination should also include a detailed evaluation for focal infection, such as exudative tonsillitis, sinus tenderness, tympanic membrane injection, and crackles or dullness on lung auscultation. Also, pharyngeal thrush should be noticed as a symptom of systemic disease. Often, the source of infection is not readily apparent.

**Diagnosis**

The initial management of the septic patient should focus on fluid and other resuscitative measures. Fluid administration should be guided by monitoring of blood pressure, cardiac output, and urine output. Central venous pressure (CVP) monitoring is essential. Urine output should be at least 0.5 mL/kg/minute. A central venous catheter should be inserted, if possible, to monitor CVP and to facilitate rapid fluid administration. Central venous pressure monitoring is used to assess cardiac function and to guide fluid therapy. The CVP should be measured in the right atrium and should not exceed 12 mm Hg. The CVP reflects the mean venous pressure in the right side of the heart and the right atrium. A catheter placed in the right atrium is a reliable indicator of intravascular volume status and helps in determining the amount of fluid to be given.

The cardiac index, even late in shock. Much of the cardiovascular compromise from septic shock is reversible, and normal cardiovascular function usually returns within 10 days.

**Pulmonary Involvement.** Involvement of the lung is often seen in the inflammatory response to infection. These effects are apparent, irrespective of the primary infection that caused sepsis. Early infiltration with neutrophils, surfactant dysfunction, and edema give way to monocyte infiltration and fibrosis. Significant right-to-left shunting, arterial hypoxemia, and intractable hypoxemia occur. The resulting morbidity is high and is a common endpoint to sepsis-related deaths.

Sepsis produces a highly catabolic state and places significant demands on the respiratory system. At the same time, airway resistance is increased, and muscle function is impaired. Irrespective of whether pneumonia is the cause of sepsis, the common pulmonary endpoint is acute respiratory distress syndrome (ARDS). ARDS is defined clinically and correlates with the pathologic finding of diffuse alveolar damage. The development of ARDS occurs hours to days after radiographic abnormalities develop. Because of alveolar-capillary membrane damage, fluid accumulates in the alveoli. Rather than being a diffuse disease, ARDS is a heterogeneous process that results in interspersed damaged and normal alveoli.

**Gastrointestinal Effects.** A shock state causes significant deleterious effects on a hollow viscus and its oxygen supply. A prolonged ileus accompanies hypoperfusion and persists beyond the perfusion deficit. Splanchnic blood flow is dependent on mean arterial pressure because there is relatively little autoregulation. Therefore, hemodynamic dysfunction may have a profound effect on viscus metabolism.

Solid organ involvement is also common. Even in the previously normal host, elevations in aminotransferases and bilirubin levels are common early in sepsis. The liver has also been implicated in the pathogenesis of sepsis; some of the mediators of sepsis are produced by the liver.

**Endocrine Disorders.** An absolute or relative adrenal insufficiency is common in sepsis. Depending on the balance of circulating cytokines, augmentation or suppression of the hypothalamic-pituitary axis is possible. IL-1 and IL-6 both activate the hypothalamic-pituitary-adrenal axis. TNF-α and corticotocin depress pituitary function. Other factors that may contribute to adrenal insufficiency in sepsis include decreased blood flow to the adrenal cortex, decreased pituitary function, and decreased pituitary secretion of adrenocorticotropic hormone due to severe stress. As a result of these interactions, the hypothalamic thermoregulatory mechanism may be reset, and temperature fluctuations may develop.

**Hematologic Abnormalities.** Sepsis causes abnormalities in many parts of the coagulation system. Endotoxin, TNF-α, and IL-1 are the key mediators. Pathologic activation of the extrinsic (tissue factor–dependent) pathway, protein C, protein S, and fibrinolysis lead to consumption of essential coagulation factors, causing DIC. The activation of the coagulation cascade produces fibrin deposition and microvascular thrombi. If these depositions are not corrected, they can compromise organ perfusion and contribute to organ failure. Tissue factor expression on monocytes is increased. This results in fibrin deposition and perhaps contributes to an increased incidence of multiorgan failure due to microvascular thrombi.

Protein C has been identified as an important modulator of inflammation and coagulation in patients with sepsis. Impairment of the protein C–dependent anticoagulation pathway is critical to the development of the thrombotic complications of sepsis. In healthy peoples, protein C is activated by a combination of thrombin and thrombomodulin. The activation of protein C results in the downregulation of many portions of the coagulation cascade, including release of tissue factor, inactivation of factors VIIIa and Va, and stimulation of fibrinolysis. It is possible that protein C activation in early sepsis is impaired because of an inflammatory cytokine–mediated downregulation of thrombomodulin. As a result, a consumptive coagulopathy ensues. This leads to increased fibrin deposition and a resulting upregulation of the fibrinolytic pathway, as identified by low plasma levels of the fibrinolytic proteins and increased fibrin split products. This sequence of events leads to consumption of coagulation factors and DIC. In late sepsis, the fibrinolytic system is suppressed.
The gastrointestinal system is the second or third (depending on the study) most common source of sepsis. A history of abdominal pain, including its description, location, timing, and modifying factors, should be sought. Further history, including time of the last bowel movement and presence of nausea, vomiting, and diarrhea, should be noted. A careful physical examination, looking for signs of peritoneal irritation, abdominal tenderness, and hyperactive or hypoactive bowel sounds, is critical in identifying the source of abdominal sepsis. Particular attention should be paid to physical findings suggestive of common sources of infection or disease—Murphy’s sign indicating cholecystitis, pain at McBurney’s point indicating appendicitis, left lower quadrant pain suggesting diverticulitis, or rectal examination revealing a rectal abscess or prostatitis.

The neurologic system is examined by looking for signs of meningitis, encephalitis, or epidural abscess, including nuchal rigidity, fevers, and change in consciousness. Lethargy or altered mentation may indicate primary neurologic disease or may be the result of decreased brain perfusion.

The genitourinary (GU) history includes queries about the presence of flank pain, dysuria, polyuria, discharge, Foley catheter placement, and genitourinary instrumentation. However, one must also remember that GU infection is a common source of infection in older patients and is a common offender in patients with nonspecific symptoms. A sexual history should assess for the risk of sexually transmitted diseases. The genital examination could reveal ulcers, discharge, penile or vulvar lesions, or the woody induration of Fournier’s gangrene. A rectal examination could reveal a tender, boggy prostate, consistent with prostatitis. A red and friable cervix, cervical discharge, or cervical motion tenderness is consistent with a sexually transmitted disease. Adnexal tenderness in a toxic-appearing woman may represent a tubo-ovarian abscess. Also, a pelvic examination in women should also include an inspection to ensure that there is no retained tampon that may serve as a source for toxic shock syndrome.

The musculoskeletal history includes the presence of any localizing symptoms to a particular joint. Redness, swelling, and warmth over a joint, especially if there is a decreased range of motion in that joint, may be signs of septic arthritis and may mandate arthrocentesis. The skin should be examined for evidence of cellulitis, abscess, wound infection, or traumatic injury. Deep injuries, foreign bodies, and fasciitis may be difficult to identify clinically. The emergency clinician should look for crepitus, bullae, or skin edema extending beyond areas of erythema that may indicate the presence of an aggressive, gas-forming organism. Back pain and fever may be signs of an epidural abscess. Local lymphadenopathy, swelling, and streaking should also be noted as signs of an advancing infection. Petechiae and purpura may represent a Neisseria meningitidis infection or DIC. Generalized erythroderma and rash may represent an exotoxin from pathogens such as Staphylococcus aureus and Streptococcus pyogenes.

A history of fevers or chills in the setting of injection drug abuse, artificial heart valve, or mitral valve prolapse should increase the suspicion for endocarditis. The emergency clinician should suspect endocarditis in the presence of a murmur or other stigmata of endocarditis (eg, splinter hemorrhages, Roth’s spots, Janeway’s lesions).

Emergency clinicians must identify the severity of illness in patients with infection and initiate early resuscitation for those with the potential of becoming critically ill. Although a patient may meet SIRS criteria, this alone has little predictive value in determining the severity of illness and mortality. There are many scoring systems that have been developed to risk-stratify illness severity. Most scoring systems are not clinically relevant and are not routinely used. The Mortality in Emergency Department Sepsis (MEDS) score is one proposed method to risk stratify ED patients with sepsis. The MEDS prediction rule assigns point values to specific clinical characteristics (Table 130.1). The total score can be used to assess risk of death. Thus, the greater the number of risk factors, the more likely a patient is to die during hospitalization. Although typically not calculated for all patients, the elements of the score may be identified and considered as a red flag when risk-stratifying a patient.

### DIAGNOSTIC CONSIDERATIONS

#### Differential Diagnoses

The sepsis syndromes represent a spectrum of disease and clinical presentations. Often, noninfectious sources can cause a syndrome that mimics that of sepsis; thus, one must keep in mind a broad differential diagnosis when approaching these patients (Box 130.2). A detailed history and physical examination are the first steps in narrowing the differential diagnosis to identify the true source.

#### Diagnostic Testing

Diagnostic studies are used to identify the type and location of the infecting organisms and define the extent and severity of the infection to assist in focusing therapy. As a result, the diagnostic approach should be tailored to the particular patient.

#### Laboratory Testing

**Hematology.** The white blood cell count can be an indicator of inflammation and activation of the inflammatory cascade. Leukocytosis is associated with infection and is incorporated in the consensus definition of sepsis; however, it is often insensitive and nonspecific, limiting its value in the ED. The febrile neutropenic patient has been shown to be at increased risk for severe infection. Thus, a neutrophil count of less than 500 cells/mm³...
A low bicarbonate level suggests acidosis and severe sepsis syndrome. A low platelet count may be seen in patients with sepsis and may be a sign of infection and inflammation. Like the white blood cell count, it is an imperfect indicator of infection. The absence of leukocytosis or bandemia does not preclude the possibility of severe sepsis nor does its presence confirm it. The hemoglobin and hematocrit levels should be determined to ensure adequate oxygen delivery in shock. Platelets are an acute-phase reactant and may be elevated in the presence of infection. Conversely, a low platelet count may be seen in patients with sepsis and septic shock. Thrombocytopenia, elevated prothrombin time, elevated activated partial thromboplastin time, decreased fibrinogen, and increased fibrin split products are associated with DIC and severe sepsis syndrome.

**Blood Chemistry.** Electrolyte abnormalities should be identified and corrected. A low bicarbonate level suggests acidosis and inadequate perfusion. An elevated anion gap acidosis in the setting of sepsis syndrome commonly represents lactic acidosis or diabetic ketoacidosis, but other causes need to be ruled out. An elevated serum creatinine concentration or decreased glomerular filtration rate signals renal dysfunction or failure, which, if due primarily to sepsis, indicates organ failure and a worse prognosis. Calcium, magnesium, and phosphorus levels should be checked.

An elevated lactate level is associated with inadequate perfusion, shock, and poorer prognosis. One study has shown a progression in mortality rate with increasing venous lactate level—a lactate level of 0 to 2.5 mg/dL was associated with a 5% mortality rate, a lactate level of 2.5 to 4.0 mg/dL, 9% mortality, and a lactate level greater than 4 mg/dL, 28% mortality. An arterial blood gas assessment may be helpful in identifying and classifying acid-base disturbances. Metabolic acidosis suggests inadequate tissue perfusion. Liver function tests can be used to identify liver failure or dysfunction. An elevated bilirubin level may suggest the gallbladder as the cause of sepsis. An elevated lipase level may represent pancreatitis as the cause of SIRS.

**Microbiology.** Proper blood, sputum, urine, cerebrospinal fluid, and other tissue culture samples are important in guiding therapy. Although the results of culture are not helpful in the initial management, culture samples should be obtained before or soon after the administration of antibiotics in the patient with sepsis syndrome. The initiation of antibiotic therapy should not be delayed significantly while waiting for culture samples to be obtained. Studies have suggested that the yield of initial blood cultures is low (5%–10%), but this is probably an artifact of the lack of reliable discriminatory guidelines for obtaining blood culture samples in the ED. Among patients with clinical sepsis, only 30% to 40% of patients will have positive cultures. The results of initial microbiologic tests, including Gram staining whenever possible, will help guide subsequent antibiotic treatment.

**Special Procedures**

We believe that a central venous pressure (CVP) line is helpful in guiding fluid resuscitation in sepsis patients. Although CVP measurements do not correlate well with volume responsiveness, a low CVP usually indicates the need for continued fluid repletion. The use of arterial lines and Swan-Ganz catheters can be helpful in managing sepsis, but they are rarely available in the ED setting. When available, arterial lines can be useful for close monitoring of hypotensive patients, especially when one or more vasopressors are being titrated to maintain an adequate blood pressure. Swan-Ganz catheters are rarely used in sepsis management in the ED, although the physiologic measurements may be useful in identifying the cause of shock and guiding fluid and inotropic therapy. Low systemic vascular resistance and high cardiac output are usually associated with sepsis, although this may vary with the stage of shock and individual patient. The science and technology of noninvasive or minimally invasive cardiac output monitoring has been evolving and, where available, may help guide fluid administration by evaluating cardiac output alone or in conjunction with a fluid challenge or passive leg raise approach.

**Radiology**

Imaging studies are generally used to identify the source of infection. A chest radiograph should be considered in patients with suspected sepsis syndrome, looking not only for a focal infiltrate representing pneumonia but also for the fluffy bilateral infiltrates indicative of ARDS. The pathophysiologic changes of ARDS are often delayed as much as 24 hours after radiographic identification. An upright chest radiograph should be considered for suspected bowel perforation to detect free air under the diaphragm.
The presence of pneumomediastinum is suggestive of esophageal perforation and current or impending mediastinitis.

Soft tissue plain radiographs of infected areas can be obtained, looking for air in the soft tissues associated with necrotizing or gas-forming infection, although plain x-rays are not sensitive for tissue infection. Periosteal thickening or bone erosion may be seen on plain radiographs of patients with osteomyelitis; a bone scan may be diagnostic. Computed tomography (CT) of superficial infections may be more helpful to quantify the extent of infection further and identify abscesses that are not readily evident on physical examination. A CT scan of the abdomen and pelvis may identify abdominal or pelvic pathologic lesions, provided there is no clear clinical indication for immediate operative intervention. Suspected disease, such as diverticulitis, appendicitis, necrotizing pancreatitis, microperforation of the stomach or bowel, or formation of an intra-abdominal abscess, may be best diagnosed by a CT scan. A head CT scan can identify septic emboli from endocarditis or increased intracranial pressure from a mass and should be considered before a lumbar puncture is performed. An abdominal ultrasound examination may be indicated for suspected cholecystitis, and a pelvic ultrasound examination may be indicated for tubo-ovarian abscess or endometritis. If endocarditis is suspected, a transesophageal cardiac ultrasound study may be performed for the detection of any valvular vegetations. Magnetic resonance imaging (MRI) can be useful to identify soft tissue infection, such as necrotizing fasciitis or epidural abscess.

**MANAGEMENT**

Early detection and appropriate treatment can reduce the mortality from sepsis. The primary goal is timely administration of appropriate antimicrobial therapy—or interventional source control as required—and maintenance of adequate tissue oxygenation and perfusion through titrated resuscitation. With early detection and early resuscitation there is increasing evidence that the natural history of sepsis can be altered. Initial resuscitation, including appropriate airway management, IV access, oxygen, early and appropriate antibiotics, fluid resuscitation, and vasopressor support, remains the foundation on which new efforts may be applied.

From a historical perspective, Rivers and associates have provided compelling evidence supporting the importance of this concept when they published a protocol of standardized timely and titrated care being used to guide resuscitation in the ED. This randomized, double-blind, placebo-controlled study showed a 16% mortality reduction in patients with severe sepsis and septic shock. The protocol, termed early goal-directed therapy (EGDT), measures targeted goals and uses a resuscitation algorithm to guide the resuscitation. The theory behind the protocol was to normalize preload and pressure and prevent tissue hypoxia by matching oxygen delivery with consumption. Use of this protocol, which facilitated earlier and more aggressive fluid resuscitation through the use of increased fluids, increased blood products, increased use of dobutamine, and greater degree of normalization of tissue hypoxia, reduced mortality at their center. The interventions in combination were likely responsible for the better outcomes in the intervention group.

The principles of EGDT, as well as efforts such as the Surviving Sepsis Campaign, helped underscore the importance of early identification and timely resuscitation. However, until 2014, the evidence in support of the formal EGDT protocol was only in the form of the original single-center trial and subsequent observational efforts. More recently, the ProCESS, ProMISE, and ARISE studies have all been large multicenter trials that sought to validate the value of EGDT. Each of the trials showed no mortality benefit to EGDT as compared to usual resuscitation measures; thus, although EGDT is one strategy to consider, it is not a superior approach from an evidence-based perspective. It is, however, important to underscore that the usual care groups in these newer trials were all identified early, received antibiotics, and received generous amounts of fluids (on average, =40–60 mL/kg in the first 6 hours across the trials), supporting the principle that early identification of sepsis, early antibiotics, and carefully titrated resuscitation should remain a core tenant.

**Respiratory Support**

Altered mental status is common in patients in septic shock, and they may require rapid airway protection. Because patients with impending respiratory failure use a disproportionately large amount of energy for the muscles of respiration, improved oxygen delivery to other organs is achieved by mechanical ventilation, sedation, and paralysis. Although there are no clear intubation guidelines, hypercapnia, persistent hypoxemia, airway compromise, and profound acidosis are valid indicators for intubation.

In addition to airway protection, intubation and mechanical ventilatory support provide positive-pressure ventilation. The pattern of injury in ARDS is such that normal lung parenchyma is adjacent to affected tissue. Therefore, increased airway pressures are required to maintain normal oxygen delivery. Current recommendations are to maintain transalveolar pressures (measured as plateau pressures) below 35 cm H₂O because increased pressures are associated with ventilator-induced lung injury. Maintenance of a relatively low transalveolar pressure with increasing end-expiratory pressure is an effective way to increase arterial oxygen delivery. The ARDSNet trial established the benefit of low tidal volumes (6 mL/kg) in mechanically ventilated patients with acute lung injury to prevent iatrogenic lung damage.

**Cardiovascular Support**

**Fluid Resuscitation**

Patients with sepsis often require IV fluid to maintain adequate perfusion. The primary reasons for this intravascular hypovolemia are venodilation and diffuse capillary leak. Initial therapy for adults with septic shock should generally be up to 2 L of isotonic crystalloid. As much as 6 to 10 L of crystalloid may be required in the first 24 hours. Fluid replacement should be titrated to clinical parameters such as heart rate, blood pressure, change in mental status, capillary refill, cool skin, and adequate urine output (0.5–1 mL/kg/hr). Normal saline (0.9%) and lactated Ringer’s solution are equally effective and neither worsens lactic acidosis. Colloids are as effective as crystalloids, but they are more expensive and less readily available. Although one should be increasingly vigilant in watching for fluid overload in patients who are predisposed, such as older adults, those with congestive heart failure (CHF) and a known impaired EF, or those with renal impairment, these patients are not precluded from volume resuscitation, as described above. Efforts to identify ways to measure regional perfusion more directly, such as direct measurement of splanchic blood flow, have been proposed. Even in the absence of global hypoxia and impaired tissue perfusion, there is evidence that regional hypoperfusion and ischemia exist.

**Vasoactive Drug Therapy**

If appropriate fluid resuscitation has failed, vasopressor support may be required (Table 130.2). Only in cases of profound hypotension should vasopressors be started before adequate fluid resuscitation has been initiated. Use of mean arterial pressure alone as an indicator of overall efficacy of therapeutic intervention is not always helpful. A mean arterial pressure of 65 mm Hg has been recommended in otherwise healthy, normovolemic adult
patients but must be correlated with other indicators of adequate perfusion, such as mental status and urine output. Patients with previously uncontrolled hypertension may require a mean arterial pressure of 75 mm Hg or even higher.

The 2012 Surviving Sepsis Campaign guidelines have provided consensus recommendations for treatment of septic shock. Fluid resuscitation remains the fundamental treatment option and should be the initial treatment. Norepinephrine should be used as the initial vasopressor, with the addition of epinephrine or vasopressin to norepinephrine as a reasonable adjunct. Vasopressin alone has been shown to be ineffective compared with norepinephrine in the initial treatment of refractory septic shock. Dobutamine should be used as the primary inotropic agent if myocardial dysfunction is evident. After an initial stabilization period, vasopressors should be titrated down, as tolerated; however, the duration of this stabilization period is variable and may be hours to days.

Norepinephrine. Norepinephrine is a mixed α- and β-agonist with minimal β1 activity and primarily functions to increase cardiac output and systemic vascular resistance. In a large study examining patients with shock from multiple causes, norepinephrine was shown to have fewer adverse events (particularly arrhythmias) compared with dopamine, which had a higher mortality rate in patients with cardiogenic shock. In another meta-analysis, norepinephrine was shown to be superior to dopamine in both in-hospital and 28-day mortality.

Compared with dopamine in septic patients, norepinephrine increases glomerular filtration and urine output equally well. It is an important component of the therapy for septic shock as a sole vasopressor or in conjunction with other vasopressors. Recommended doses are 8 to 12 µg/min.

Dopamine. Dopamine is also often used for septic shock unresponsive to adequate volume expansion. Dopamine is the immediate precursor of norepinephrine and epinephrine. It is primarily an α1- and β1-receptor agonist. Although low doses alone are not effective, they may be effective in combination with other agents. So-called renal dose dopamine has not been shown to reduce mortality or decrease dialysis dependence and should not be used. Dosages higher than 20 µg/kg/min may produce significant vasoconstriction. Persistent tachycardia, decreased partial pressure of arterial oxygen, and increased pulmonary artery occlusion pressure are common side effects of dopamine use.

Phenylephrine. Phenylephrine is a selective α1-agonist, increasing systemic vascular resistance without significant changes in cardiac output. It can produce a reflexive bradycardia or suppression in cardiac output. A single small study has shown that phenylephrine is effective in restoring perfusion in patients with septic shock refractory to dopamine or dobutamine. Another small study has demonstrated that phenylephrine is less effective than norepinephrine in the treatment of hypotension in septic patients; however, there was no difference in other measured hemodynamic parameters, including oxygen delivery. Phenylephrine does not impair cardiac and renal function and may be a good choice when significant tachyarrhythmia limits the use of other agents.

Epinephrine. Epinephrine is a potent mixed α1- and β-agonist. Epinephrine infusion is also associated with increased oxygen consumption, increased systemic lactate concentrations, and decreased splanchnic blood flow. The rise in the lactate level is short term, and there is no evidence regarding its long-term effects. As a result of all the possible adverse effects of epinephrine, it is currently recommended only for those patients who are unresponsive to other vasopressors. Adverse effects may include peripheral vasospasm and a critical reduction in extremity perfusion, leading to gangrene.

Vasopressin. Vasopressin is a naturally occurring peptide that is synthesized as a large prohormone in the hypothalamus. In states of septic shock, there is an early surge of vasopressin followed by a profound drop in circulating vasopressin levels. This is the foundation for the use of vasopressin as an adjunct therapy for patients with severe sepsis. Vasopressin should not be used as the sole initial therapy for refractory septic shock. In a well-designed randomized trial, investigators demonstrated no change in mortality for patients with severe sepsis when vasopressin was added to catecholamine vasopressors.

Dobutamine. Dobutamine is a mixed α1- and β1-agonist. In dosage ranges from 2 to 28 µg/kg/min, the cardiac index is increased at the expense of heart rate. In addition, decreased splanchnic blood flow is common. Dobutamine should be used in patients with depressed cardiac index and persistent hypoperfusion in spite of adequate volume expansion and the use of other vasopressor agents. In patients undergoing formal, early, goal-directed therapy, when preload, perfusion pressure, and oxygen-carrying capacity have been normalized and a low ScvO2 persists, dobutamine is used to increase cardiac output and oxygen delivery. One study has suggested that survival in sepsis is associated with the patient’s increase in stroke volume in response to dobutamine.

Bicarbonate
Bicarbonate supplementation was previously the standard treatment for patients with presumed lactic acidosis. Current consensus is that it should be reserved for severe acidemia (pH < 7.0–7.2) because there may be a paradoxical decrease in intracellular pH as a result of diffusion of soluble carbon dioxide across the cell membrane. Alternatively, hyperventilation has been suggested to help increase systemic pH.

Antibiotics
Early antibiotic therapy should target the nidus of infection if known. If the patient’s condition permits, appropriate culture specimens should be obtained before the administration of broad-spectrum antibiotics (Table 130.3). Surgically correctable conditions, such as intra-abdominal abscesses, perforated viscus, retained products of conception, or retained foreign body (eg, a tampon), should be treated concurrently. Antibiotics should be administered as soon as possible in patients with serious infections. Although some observational studies and national benchmarks have called for the administration of antibiotics within a predefined time period of 3 hours from ED presentation, a comprehensive meta-analysis failed to support an association between

antibiotics administered after 3 hours and mortality. Thus, early antibiotics are important, but their exact timing remains undefined.

In the absence of an obvious source of infection, the use of broad-spectrum antibiotics is recommended. The specific agent depends on many variables, including institutional preference and local resistance patterns. As results from cultures become available, therapy should be modified. There is no consensus about the need for double or triple antibiotic coverage for particular organisms, although it is common practice to double-cover virulent organisms, such as Pseudomonas aeruginosa, as well as areas commonly infected with multiple organisms, such as the peritoneum. With increasing rates of methicillin-resistant organisms, combinations that include nonpenicillin choices may be warranted.

Steroid Therapy

It has been nearly 40 years since the first treatment attempts to block inflammation in sepsis. Because sepsis involves a systemic inflammatory response, corticosteroids are a logical treatment modality as antiinflammatory agents. Physicians have been working for decades to prove or disprove their value. Steroids appear to be more effective in reducing the amount of time patients spend in a hypotensive state, but increase the rate of secondary infection, contributing to a null effect overall. At this time, we believe that the role of steroid therapy in sepsis remains controversial and recommend their use in patients on chronic steroid therapy when there is refractory cardiovascular insufficiency, despite maximal supportive therapy and replacement therapy.

DISPOSITION

Once ED management is complete, patients who are deemed at increased risk should be admitted to the hospital into a setting that is deemed appropriate for the severity of the patient’s condition. For example, in patients who remain hypotensive, are on vasopressors, or who are unstable and require more frequent monitoring, the intensive care unit may be appropriate. Other patients who are more stable but still require monitoring and perhaps IV therapy may be admitted to a hospital ward. Finally, in certain cases, patients initially meeting sepsis criteria but who are not severely ill (eg, young patients with pharyngitis) may be appropriate for discharge.

a| Pending microbiologic identification of organism and sensitivity.
Sepsis is a progression of disease due to a dysregulated inflammatory cascade, leading to organ dysfunction and circulatory compromise in severe cases.

Sepsis is subtle and often difficult to detect, so the emergency clinician should maintain a high index of suspicion when assessing patients in the ED.

Older adults, immunocompromised and neutropenic patients, and patients with multiple comorbidities are at increased risk for the development of sepsis syndromes.

A thorough history and physical examination should guide the diagnostic evaluation.

Early treatment should focus on appropriate identification, improvement of tissue perfusion (through administration of fluids and vasopressor medications), improvement of tissue oxygenation (through administration of oxygen and positive-pressure ventilation), administration of antibiotics, and early identification of infections requiring surgical management.

Prompt administration of antibiotics is essential and should be based on the suspected source of infection.

CHAPTER 130: QUESTIONS & ANSWERS

130.1. Which of the following patients meets the criteria for systemic inflammatory response syndrome (SIRS)?
A. 6-year-old boy with pneumonia, temperature 39.0°C (102.2°F)
B. 21-year-old woman with abdominal pain, temperature 38.3°C (100.9°F)
C. 53-year-old man with respirations, 30 breaths/min, white blood cell (WBC) count, 16,000 cells/mm³
D. 74-year-old woman with chest pain, heart rate 130 beats/min
E. 81-year-old man with WBC count, 2700 cells/mm³, heart rate, 73 beats/min

Answer: C. SIRS is defined as two or more of the following—tachycardia, tachypnea, temperature higher than 38°C (100.4°F) or lower than 35°C (95°F), high or low WBC count, or bandemia. Sepsis is SIRS with infection. Severe sepsis includes organ dysfunction. Septic shock involves systolic blood pressure below 90 mm Hg.

130.2. Septis is characterized by which of the following?
A. Depression of arachidonic acid metabolites
B. Depression of tumor necrosis factor levels
C. Increased endogenous anticoagulant levels
D. Prolonged suppression of nitric oxide levels
E. Prolonged suppression of vasopressin levels

Answer: E. Clinical sepsis is induced by sustained levels of proinflammatory and procoagulant mediators. Cytokines (interleukin-1, interleukin-6, and tumor necrosis factor alpha) and prosta glandins are primary mediators. Nitric oxide synthase is upregulated, resulting in sustained elevations of the serum nitric oxide level, with subsequent vasodilations. Sustained suppression of vasopressin adds to this sometimes refractory vasodilated state.

130.3. Which of the following statements regarding septic shock is true?
A. Cardiac output is always decreased.
B. Much of the cardiac decompensation is reversible.
C. Systemic vascular reserve is high.
D. The ejection fraction is always increased.
E. Ventricular dilation is unusual.

Answer: B. Sepsis affects myocardial function and peripheral vascular tone. The systemic vascular resistance is usually markedly decreased. Cardiac output is generally increased because of a compensatory tachycardia that can at least partially overcome the ventricular dilation and depressed ejection fraction. The myocardial effects are typically reversible.

130.4. What are the two most common sources of infection in cases of sepsis?
A. Genitourinary > respiratory
B. Musculoskeletal > genitourinary
C. Respiratory > gastrointestinal
D. Respiratory > genitourinary
E. Skin > respiratory

Answer: C. Epidemiology studies show that pneumonia is the most common cause of sepsis, followed by an intra-abdominal source. However, a careful investigation to identify the source of infection should occur.

130.5. In most chemotherapy patients, which neutrophil count should prompt admission, isolation, and empirical antibiotics?
A. <250 cells/mm³
B. <500 cells/mm³
C. <750 cells/mm³
D. <1000 cells/mm³
E. <2000 cells/mm³

Answer: B. Patients with an ANC <500 cells/mm³ are at increased risk of infection; thus, a conservative approach should be taken in these patients.

130.6. Among patients with clinical septic shock, which percentage will have positive blood cultures?
A. 0%–30%
B. 30%–60%
C. 60%–90%
D. 90%–100%
E. Varies according to patient comorbidities

Answer: B. While blood cultures are perhaps a gold standard for identification and isolation of bacteria, they may negative, even when the etiology of illness is clearly infectious. Empiric antibiotic treatment in the ED remains a standard approach.

130.7. A 65-year-old man presents with blood pressure of 88/40 mm Hg, heart rate of 105 beats/min, respiratory rate of 24 breaths/min, 
O₂ saturation of 92%, and temperature of 38.5°C (101.3°F). Fluid resuscitation, oxygen, and empirical antibiotics are begun. Blood pressure after 2 L of saline is 98/50 mm Hg. A central venous catheter is placed, with a central venous pressure of 11 mm Hg. A venous blood gas sample drawn from this catheter shows hematocrit of 24%, PO₂ of 34 mm Hg, PCO₂ of 46 mm Hg, pH of 7.29, and O₂ saturation of
63%. O₂ saturation by pulse oximeter is now 96%. What is the most appropriate next step according to the early goal-directed therapy protocol?

A. Dopamine, 10 µg/kg/min  
B. Endotracheal intubation  
C. Packed red blood cell transfusion  
D. Phenylephrine, 50 µg/min  
E. Saline 0.9%, 2 L more

**Answer: C.** For the optimal management of sepsis, central venous pressure monitoring (ideally with oximetric capabilities) and mixed venous blood gas monitoring are indicated. This patient meets criteria for septic shock. Intermittent central venous (eg, mixed) blood gas analysis is likely to be adequate. Therapeutic targets are a central venous pressure of 8 to 12 mm Hg in the nonintubated patient and a mixed venous O₂ saturation of 70% (review of the oxyhemoglobin desaturation curve reminds us that 75% is normal). After volume resuscitation, this patient still had a low mixed venous saturation, indicating inadequate peripheral oxygen delivery and increased extraction by the tissues. With O₂ saturation nearly normal (96%), the only way to increase oxygen delivery is by red blood cell transfusion to increase the plasma hemoglobin concentration.
FROSTBITE

Principles

Background

Unlike other mammals that live outside the tropics, humans are susceptible to local cold injuries. Local cold injuries may occur in conjunction with systemic hypothermia. Frostbite involves tissue freezing with formation of ice crystals in the tissues. Immersion injury (trench foot) is a nonfreezing injury that results from exposure to wet cold. Pernio (chilblains) is a nonfreezing injury that occurs in susceptible individuals, usually after exposure to dry cold.

Historically, frostbite has been a disease of wars. Frostbite caused over 1 million casualties in World Wars I and II and the Korean War. Trench foot was common in the world wars and during the conflict in the Falkland Islands. Frostbite and immersion injuries are risks for anyone who ventures outdoors in severely cold conditions for recreation or work. Homeless or displaced people are also at risk, especially during disasters.

Physiology

The human body attempts to maintain a core temperature of about 37°C (98.6°F). Skin cooling activates the anterior hypothalamus, causing catecholamine release, thyroid stimulation, shivering thermogenesis, and peripheral vasoconstriction. People are physiologically adapted to tropical conditions. In cold conditions, humans have a limited ability to protect themselves against decreased core temperature. Behavioral responses are far more effective if adequate clothing or shelter is available.

Cutaneous circulation is one of the keys to maintenance of a constant core temperature. Baseline cutaneous circulation greatly exceeds nutritional requirements. In warm conditions, the skin acts as a radiator to shed excess heat. Cold-induced vasoconstriction can reduce flow to 10% of baseline without damage to the skin.

During cold stress, peripheral vasoconstriction limits radiant heat loss. Acral skin structures (eg, fingers, toes, ears, nose) contain a plethora of arteriovenous anastomoses. These anastomoses shut down in the cold, causing drastic reductions in blood flow. This so-called life-versus-limb mechanism is a means of preventing systemic hypothermia.

Cooling of digits to 15°C (59°F) results in maximal peripheral vasoconstriction, with minimal blood flow. Continued cooling to 10°C (50°F) produces cold-induced vasodilation (the so-called hunting response), a counterbalance to cold-induced vasoconstriction. Vasodilation follows 5- to 10-minute cycles, interrupting vasoconstriction and protecting the extremity. Eskimos, Lapps, and other northern peoples have stronger cold-induced vasodilation than individuals from tropical regions. There is evidence of adaptation in addition to genetic control.

Pathophysiology

Frostbite occurs only when the tissue supercools well below 0°C (32°F). The required temperature is at least −4°C (24.8°F) and may be as low as −10°C (14°F) under some conditions. Tissue injury occurs due to structural damage to cells from ice crystal formation and to microvascular thrombosis and stasis. In the prefreeze phase, tissue temperatures drop below 10°C (50°F), and cutaneous sensation is lost. Before ice crystals form, microvascular vasoconstriction can occur, with endothelial leakage of plasma into the interstitium. In the freeze-thaw phase, the timing, location, and rate of ice crystal formation depend on conditions. Wind and moisture increase the freezing rate. The phases vary with the extent and rapidity of the cold response and may overlap (Box 131.1).

**Frostbite**

*Ken Zafren | Daniel F. Danzl*

**CHAPTER 131**

Frostbite and Nonfreezing Cold Injuries

Except in extremely cold conditions, ice crystal formation initially occurs extracellularly. Water then exits the cell to maintain osmotic equilibrium. Cellular dehydration increases the intracellular osmolarity and electrolyte concentrations. After approximately one-third of the cellular volume is lost, the cell collapses and dies, even if there is no direct structural damage from ice crystals. Extracellular crystallization increases the tissue pressure on cell membranes and vascular structures. Sludging, stasis, and cessation of flow occur at the capillary level.

A third phase, progressive microvascular collapse, first affects venules and then arterioles. Red blood cells sludge and form microthrombi during the first few hours after the tissues are thawed. Factors that decrease flow include hypoxic vasoconstriction, hyperviscosity, and direct endothelial cell damage. Ischemic conditions extend the surrounding injury. Plasma leakage and arteriovenous shunting result in thrombosis, increased tissue pressure, ischemia, and necrosis.

Progressive dermal ischemia is partially mediated by thromboxane. Prostaglandins are found in clear vesicles. When subdermal vascular plexi are injured, hemorrhagic blisters develop, which also contain prostaglandins. Arachidonic acid breakdown products released from underlying damaged tissue into blister fluid include prostaglandins and thromboxane. These mediators produce platelet aggregation, vasoconstriction, and leukocyte immobilization.

Injury to the microvasculature is the ultimate determinant of progressive tissue damage. Endothelial cells are very susceptible to freezing injury. After thawing, the vasculature may be temporarily patent. Platelet and erythrocyte aggregates promptly clag and
Clinical Features

The term frostnip refers to a superficial freezing injury manifested by transient numbness and tingling that resolves after rewarming. No tissue destruction occurs. The most common presenting symptom of frostbite is numbness, which is nearly universal. All patients have initial sensory deficits in light touch, pain, or temperature. Anesthesia is produced by intense vasoconstrictive ischemia and neurapraxia, usually in acral areas and distal extremities. Fingers, toes, nose, ears, and penis are the specific areas at risk. Patients often complain of clumsiness and report a so-called block of wood sensation in the extremity. Complete anesthesia in a cold digit suggests a severe injury.
Initial presentation of frostbite is often deceptively benign. Most patients do not arrive in the emergency department (ED) with frozen insensate tissue. Frozen tissues feel hard and appear mottled or violaceous white, waxy, or pale yellow (Fig. 131.1). In severe cases, it is not possible to roll the dermis over bony prominences. Rapid rewarming results in an initial hyperemia, even in severe cases (Fig. 131.2). After thawing, there is usually partial return of sensation until blebs form.

Favorable initial symptoms after rewarming include normal sensation, warmth, and color. Soft pliable subcutaneous tissue suggests a superficial injury. A residual violaceous hue after rewarming is ominous (Figs. 131.3 and 131.4). Early formation of large blebs with clear fluid that extend to the tips of the digits (Fig. 131.5) is more favorable than a delayed appearance of smaller, more proximal hemorrhagic vesicles that are produced by damage to subdermal vascular plexi (Fig. 131.6). Bullae and vesicles usually form in 1 to 24 hours.

Lack of edema formation suggests significant tissue damage. Postthaw edema usually develops within 3 hours. In severe cases, frostbitten skin forms a black dry eschar that mummifies, with apparent demarcation (Figs. 131.7 and 131.8).
Historically, frostbite, like burns, was classified into degrees of injury. Anesthesia and erythema were considered to be first-degree frostbite. Superficial vesiculation surrounded by edema and erythema indicated second-degree frostbite. Third-degree frostbite produced deeper hemorrhagic vesicles. Fourth-degree injuries extended into subcutaneous, tissues, including bones and muscles.

Classification by degrees does not correlate well with the amount of tissue damage and is therapeutically misleading. A simpler, more useful classification divides frostbite into superficial or mild frostbite, which does not result in loss of tissue, and deep or severe frostbite, which causes loss of tissue. It is difficult to predict the amount of tissue loss at the time of initial presentation.

Significant pain usually accompanies reestablishment of perfusion. A dull continuous ache evolves into a throbbing sensation in 48 to 72 hours. This may persist until tissue demarcation occurs weeks to months later. Short-term and long-term sequelae are common (Box 131.3).

**Differential Diagnosis**

The differential diagnosis of frostbite is limited. Burns, cellulitis, gangrene (from other causes), vascular injuries, diabetic neuropathies, and pressure necrosis can resemble frostbite, but can usually be distinguished based on history. Severe, nonfreezing, cold injuries can also mimic frostbite. After thawing, before edema develops, frostbitten areas may appear deceptively normal for a few hours.

**Diagnostic Testing**

Except in patients being considered for thrombolytic therapy, diagnostic imaging has a limited role in the emergency care of patients with frostbite. Ancillary diagnostic imaging techniques can be used to help grade the severity of injury, but no technique consistently predicts tissue loss at the time of initial examination.

Patients with frostbite should undergo laboratory testing and imaging, as indicated for coexisting conditions and injuries. We recommend obtaining baseline plain radiographs of frostbitten tissue. Follow-up radiographs may begin to demonstrate specific frostbite abnormalities 4 to 10 weeks after injury.

Patients being considered for thrombolytic therapy should undergo computed tomography (CT) or magnetic resonance (MR) angiography for intraarterial therapy or radionuclide scanning for intravenous (IV) therapy. Otherwise, angiography or scintigraphy should be delayed.

Magnetic resonance imaging (MRI) of developing hyaline cartilage can demonstrate physeal injury, which has the largest impact on longitudinal growth. Bone scanning may also help predict prognosis early in the hospital course.

**Management**

**Prehospital**

Napoleon's Surgeon General, Baron Larrey, first recorded the disastrous effects of the freeze-thaw-refreeze cycle. During the 1812 to 1813 Russian campaign, soldiers would thaw frozen extremities directly over open fires, only to have them refreeze, with resultant tissue destruction. Unfortunately, gangrene was misattributed to rapid thawing. Gradual thawing, often including friction massage with snow, became the standard treatment regimen until the 1950s. In 1961, William Mills, Jr., popularized rapid thawing in warm water after extensive research with severe Alaskan frostbite cases.

Field rewarming of frozen tissue is rarely practical. If possible, constricting or wet clothing should be removed and affected areas
SECTION 131 Frostbite and Nonfreezing Cold Injuries

CHAPTER 131 Frostbite and Nonfreezing Cold Injuries

should not be delayed while waiting for the results of laboratory and radiographic studies. Most patients are volume-depleted, partly due to poor oral intake and hypothermia-induced cold diuresis, and should receive volume replacement with crystalloid at 40°C (104°F) to decrease blood viscosity and sludging.

Thaw. Frozen or partially thawed tissue should be rapidly warmed by immersion in gently circulating water that is carefully maintained at a temperature of 37°C–39°C (98.6°F–102.2°F). A whirlpool is ideal, but a large container can be used for the hands or feet. Do not let frostbitten areas bump or rub against the side of the container. Water warmer than 39°C (102.2°F) does not warm significantly faster, but causes more pain. Tissue can suffer thermal injury when the water temperature exceeds 42°C (107.6°F). Rewarming should be continued until distal erythema is noted. The part should feel pliable, which usually requires 10 to 30 minutes of submersion. Encourage gentle motion, but do not massage. Premature termination of rewarming results in a partial thaw, with increased tissue damage.

Parenteral analgesia is often indicated during rewarming. Reperfusion may be intensely painful, with throbbing, burning pain and tenderness. Sensation is usually diminished after thawing until it disappears with bleb formation.

Patients with completely frozen extremities are usually hypothermic and at risk for significant fluid and electrolyte fluxes during rewarming. The acute thawing of large amounts of distal musculature extinguishes peripheral vasoconstriction, resulting in a sudden return of cold, hyperkalemic, acidotic blood to the central circulation. This can produce what is termed core temperature afterdrop, with ventricular fibrillation. In the most severe cases, extracorporeal rewarming should be considered (Box 131.4).

**Emergency Department Rewarming Protocol**

**PRETHAW**
- Assess Doppler pulses and appearance.
- Protect part—no friction massage.
- Stabilize core temperature.
- Address medical and surgical conditions.
- Administer volume replacement as indicated.

**THAW**
- Provide parenteral opiate analgesia as needed.
- Administer ibuprofen 400–600 mg (or aspirin, 325 mg).
- Immerse part in circulating water at 37°C–39°C (98.6°F–102.2°F), monitored by thermometer.
- Encourage gentle motion, but do not massage.

**POSTTHAW**
- Dry and elevate.
- Aspirate or débride clear vesicles.
- Débride broken vesicles and apply topical antibiotic or sterile aloe vera ointment every 6 hours.
- Leave hemorrhagic vesicles intact.
- Administer tetanus prophylaxis if indicated.
- Provide streptococcal prophylaxis if high risk.
- Consider phenoxymenzamine in severe cases.
- Perform imaging, including angiography, if thrombolysis may be indicated.
- Carry out thrombolysis, if indicated and available.
- Obtain admission photographs.

In general, the longer tissue has been frozen, the greater the extent of cellular damage. However, rewarming should not be initiated in the field if there is any possibility that thawing will be interrupted or incomplete or that tissue will refreeze during evacuation. Tissue refreezing is disastrous. It is better to walk to safety on frozen feet if rescue will be delayed. When evacuation is not possible, rapid field rewarming, preferably in water at 37°C to 39°C (98.6°F–102.2°F), may be the only option.
Postthaw. We keep injured extremities elevated to minimize edema formation, apply sterile dressings loosely, and handle frostbitten areas gently. Due to cold–induced anesthesia, soft tissue injuries are often not appreciated by the patient or emergency clinician. Persistent cyanosis in the extremities after a complete thaw may reflect increased compartment pressure. Tissue should be monitored carefully, but decompression fasciotomies are usually not necessary during initial treatment.

Although there is no definitive supporting evidence, we recommend the use of topical aloe vera with oral aspirin or ibuprofen. Topical aloe vera every 6 hours inhibits thromboxane when applied directly to frostbitten areas. It has not been shown to improve tissue salvage. Aspirin and ibuprofen inhibit the arachidonic acid cascade, although there is no evidence of efficacy for either agent. Some authors prefer ibuprofen because it also produces fibrinolysis. However, aspirin is used widely, especially in Europe.

Large clear blisters can be left intact, débrided or aspirated. We débride broken or intact nonhemorrhagic blisters. Hemorrhagic blisters should be aspirated rather than débrided. When hemorrhagic blisters are débrided, secondary desiccation of deep dermal layers appears to extend the injury.

Although there has been no demonstrated benefit of penicillin for streptococcal prophylaxis, it is used routinely in some centers. We recommend against using prophylactic antibiotics for frostbite unless there is associated gross contamination. Tetanus can occur after frostbite. Tetanus prophylaxis should follow usual wound care guidelines.

Thrombolytic therapy has been used to treat microvascular thrombosis in frostbite. In one retrospective study, IV tissue plasminogen activator (tPA) and heparin reduced predicted digit amputations in severe frostbite. In another study, intraarterial tPA decreased the incidence of amputations when it was administered within 24 hours of thawing. Selection and treatment guidelines have been proposed for thrombolysis. Thrombolysis should be reserved for patients with severe injuries likely to produce significant tissue loss, such as frostbite that extends to the proximal phalanges. If there are no contraindications to thrombolysis, and frostbite can be treated within 24 hours of thawing, angiography is performed with intraarterial vasodilators. If flow is not reestablished, continuously infuse intraarterial, catheter-directed tPA to a maximum dose of 1 mg/hr. Administer heparin concurrently and continue for 72 to 96 hours. Intraarterial thrombolysis should only be performed in centers that have intensive care capabilities and are familiar with the technique. An alternative approach combines systemic IV thrombolytic therapy with subsequent vascular evaluation by technetium scanning. One suggested prognostic strategy uses appearance after rapid rewarming, coupled with early bone scanning, to predict eventual tissue loss.

There are many unproven therapies for frostbite, including low-molecular-weight dextran, vasodilator therapy, and phenoxycbenzamine. Hyperbaric oxygen may accelerate demarcation, but has not been shown to increase tissue salvage in severe frostbite.

Iloprost, a prostacyclin analogue, has vasodilatory properties that mimic a chemical sympathectomy. The risk of amputation was significantly lower in a controlled trial of patients with severe frostbite who received IV iloprost plus aspirin after thawing. Selected patients in this series with severe frostbite were also treated with recombinant tPA.

Chemical or surgical sympathectomy does not decrease tissue loss. Surgical sympathectomy produces a smoother initial clinical course but no long-term benefits, with the possible exception of decreased long-term pain. Forearm nerve blocks produce a chemical sympathectomy that increases finger skin temperature. Although prehospital wrist blocks may achieve rapid pain control with rewarming, there have been no systematic studies of outcomes.

Disposition
Patients with superficial frostbite can be safely discharged to a warm place unless there is another indication for admission. Social services can be consulted if the patient is homeless. All other patients with frostbite should be admitted for further evaluation and treatment. Transfer or further consultation is indicated when the admitting service lacks experience in the care of frostbite. Patients who potentially meet the criteria for intraarterial thrombolysis should be transferred to a suitable facility if thrombolysis can be initiated after transfer within 24 hours of thawing.

NONFREEZING COLD INJURIES

Principles
Nonfreezing cold injury occurs when tissue fluids have not frozen. The most common nonfreezing cold injury is immersion injury, often referred to as trench foot, although the hands may also be affected. This is a significant threat during recreational activities and military expeditions in cold wet climates. Trench foot is produced by prolonged exposure to wet cold at temperatures above freezing. It usually develops slowly over several days and results in neurovascular damage. Immersion injury commonly develops while a person is wearing socks that are wet from immersion in water.

Immersion injury can also occur from sweat, especially with the use of neoprene socks, vapor barrier boots, or constrictive gaiters. People who soak their feet for hours in cool water for pain relief are also at risk. Bullae and tissue loss in immersion injury may be due to pressure necrosis rather than to cold injury. Most patients with severe immersion injury are military personnel who have worn boots continuously for days or weeks. Prevention of immersion injury may require frequent drying of feet and socks.

Pernio (chilblains) is a mild form of cold injury that often follows repetitive exposure in susceptible individuals. Chilblains can also occur with little or no exposure to cold in individuals who have underlying diseases.

Clinical Features
Immersion Injury
Immersion injury is classically described in four stages. In the first stage (during cold exposure), numbness is the most common symptom. The extremities may appear bright red, but soon become pale or white due to extreme vasoconstriction (Fig. 131.9). There is no pain or swelling at this stage.

In the second stage (following cold exposure) after removal from a cold environment and during rewarming, peripheral blood flow slowly returns, and the extremities become a mottled pale blue. This change may be subtle in highly pigmented skin. The extremities remain cold and numb, although pain and edema can result from active rewarming. This stage usually lasts for a few hours, but occasionally persists for several days.

In the third stage (hyperemia), blood flow increases markedly. The extremity suddenly becomes hot and red, with bounding pulses, while the microcirculation is sluggish, as evidenced by prolonged capillary refill. Dependent redness (rubor) and pallor on elevation may occur due to vasomotor paralysis. At the same time, numbness gives way to severe pain with hyperalgiesia, even to light touch. Edema often develops. In severe cases, bullae, like those seen in frostbite, can form. In rare cases with tissue loss,
Diagnostic Testing

Infrared thermography in response to cold stress may support the diagnosis of immersion injury and help assess severity. Diagnostic testing in patients with pernio is directed toward finding an underlying condition.

Management

Immersion Injury

Hypothermia, if present, should be treated before treating nonfreezing cold injuries. Volume replacement with warm IV fluids should be given if the patient is clinically volume-depleted. Immersion injuries should be allowed to rewarm slowly. Rapid rewarming or rubbing may worsen the injury. No medications are known to be helpful. Local cooling lowers metabolic requirements and improves pain and edema. Cooling should be continued until hyperemia resolves.

Pernio

There is no standard treatment for pernio. We recommend drying the skin if it is damp and gentle massage if the patient can tolerate it. Avoid warming the skin above 30°C (86°F). Pernio is very painful and may require opioid analgesia. Nifedipine (20–60 mg daily) is the only medication that has been shown to be potentially effective in the treatment of severe pernio.

Disposition

Many patients with significant immersion injury require admission for pain control, as well as assistance with activities of daily living. Patients with mild immersion injuries can be discharged if there are no other indications for admission and the patient can be released to a warm environment. Patients with pernio are usually managed as outpatients.

**CHAPTER 131: QUESTIONS & ANSWERS**

131.1. What is the most common presenting symptom of frostbite?
A. Blisters
B. Discoloration
C. Numbness
D. Pain
E. Skin sloughing

**Answer:** C. Numbness is the presenting symptom in more than 75% of cases. Even when numbness is not the presenting symptom, it is still present in all cases of frostbite. Pain often does not develop until rewarming and the reestablishment of perfusion. Discoloration, blister formation, and skin sloughing can all occur but are often delayed by hours to days or weeks.

131.2. A 27-year-old man presents complaining of numb feet and hands. Several hours ago, he returned from an overnight hike in some nearby mountains. He reports that the temperature was consistently below −10°C (14°F). After immediate rewarming, you reexamine his hands and feet. Which of the following, if present, would portend the worst prognosis?
A. Bounding pulses
B. Edema
C. Large clear vesicles
D. Pale color
E. Violaceous hue

**Answer:** E. After rewarming, extremities may still remain slightly pale or become slightly erythematous, both of which are normal. A violaceous hue indicates more severe damage. Edema is actually an expected and favorable finding. Lack of edema again indicates severe damage and lack of circulation. Large clear vesicles are also expected and are not poor prognostic indicators. However, the formation of small hemorrhagic vesicles is a poor prognostic sign. These vesicles usually form somewhat later in the course. Pulsellessness would be a poor sign, but return of pulses or even bounding pulses should be expected.

131.3. At initial presentation of a frostbite injury, which imaging modality is indicated?
A. Computed tomographic angiography
B. Doppler ultrasonography
C. Magnetic resonance angiography (MRA)
D. Plain film radiography
E. Scintigraphy

**Answer:** D. Multiple studies, including the other four listed, have been tested to predict the extent of tissue loss accurately, but none have been consistently successful. Plain film radiography is indicated to evaluate for other injury. Because frostbite results in near-total anesthesia of the extremity, accompanying skeletal injury can go undiagnosed. Subsequently, MRA may help predict the line of demarcation for tissue loss. The patient should be advised that, in severe cases, accurate prediction of eventual tissue loss is not possible at presentation.

131.4. What is the best method to rewarm a frostbitten extremity?
A. Manual friction
B. Room temperature air convection
C. Room temperature water immersion
D. Warm air convection
E. Warm water immersion

**Answer:** E. Ideally, water should be 37°C to 39°C (98.6°F–102.2°F). Additional damage can be caused when the water temperature exceeds 42°C (107.6°F). In general, water temperature of 35°C to 39°C (95°F–102.2°F) is rapidly effective, well tolerated, and will not cause additional injury. Typically, 10 to 30 minutes is required. Analgesia is necessary during rewarming because pain should be expected. Friction is contraindicated because this will almost always cause additional injury. Room temperature air, water, and warm air will all slowly thaw a frostbitten extremity, but the length of time frozen is directly related to the extent and degree of injury, so rewarming should be accomplished using the quickest measures.

131.5. What is the most common error made when treating frostbite injury?
A. Débridement of broken blisters
B. Inadvertently causing systemic hyperthermia during thawing
C. Premature termination of thawing
D. Use of nonsteroidal antiinflammatory drugs (NSAIDs) for analgesia
E. Use of thrombolytic agents to restore blood flow

**Answer:** C. Often, a patient’s extremities are initially thawed appropriately with circulating warm water, but the thawing is terminated because of severe pain. Pain during thawing is typical and should be expected. Parenteral analgesics are necessary. Broken blisters should be débrided, clear blisters can be aspirated or débrided, and hemorrhagic blisters should be left intact. Inadvertently causing systemic hypotension can occur because many frostbite patients are already cold. Submerging an extremity in warm water will cause local vasodilation and may actually cause systemic hypothermia. An NSAID is the drug of choice for analgesia because the inhibition of thromboxane and arachidonic acid may improve long-term outcome (this is controversial, but NSAIDs are still effective). Thrombolytic agents, such as tissue plasminogen activator (tPA; in small studies), improve outcome and decrease digit amputations.
Accidental Hypothermia

Ken Zafren | Daniel F. Danzl

**PRINCIPLES**

**Background**

Reported reanimations of profoundly cold victims in prolonged cardiac arrest and the emergence of therapeutic hypothermia after cardiac arrest have made hypothermia a compelling topic. The lowest recorded core temperature in accidental hypothermia with successful resuscitation was 13.7°C (56.7°F) in a 29-year-old Norwegian physician; cardiopulmonary resuscitation was initiated at the scene. The 9-hour resuscitation included 179 minutes of cardiopulmonary bypass.

The treatment of accidental hypothermia has been controversial. Biblical references have recounted the truncal rewarming of King David by a damsel. Various remedies, including rubbing of the extremities with hot oil, were mentioned by Hippocrates, Aristotle, and Galen.

Cold weather has had a major impact on military history. Hannibal lost nearly half of his army of 46,000 while traversing the Alps in 218 BCE. The winter of 1777 took its toll on Washington’s troops at Valley Forge. Napoleon’s chief surgeon, Baron Larrey, reported that only 350 of the 12,000 men in the 12th division survived the cold during their retreat from Russia in 1812. Those soldiers who were rapidly rewarmed closest to the campfire died. Many lessons were relearned during both world wars. Pilots and U-boat crews perished in the cold waters of the North Atlantic. The toll continues today in the high mountains of Asia.

Cold-related tragedies also affect civilians, including hunters, skiers, climbers, boaters, swimmers, and survivors of natural disasters. Hypothermia can occur in a wide range of climates and seasons. Large numbers of cases occur in urban settings. Primary hypothermia fatalities can be classified as accidental, homicidal, or suicidal. Death certificate data have underreported mortality from secondary hypothermia, in which cold complicates systemic diseases. The effect of cold on mortality from cardiovascular and neurologic disorders is greatly underestimated.

Hypothermia is defined as a core temperature below 35°C (95°F). Many variables contribute to the development of accidental hypothermia. Exposure, old age, poor health, inadequate nutrition, and various medications and intoxicants can decrease heat production, increase heat loss, or interfere with thermobility. Compensatory responses to heat loss through conduction, convection, radiation, and evaporation are often overwhelmed by exposure, even in healthy persons. Medications can also interfere with thermoregulation. Central nervous system (CNS) problems may limit the efficiency of thermoregulation.

**Physiology of Temperature Regulation**

Human basal heat production increases with food ingestion, muscle activity, fever, and acute cold exposure. Cold stress increases preshivering muscle tone, potentially doubling heat production. Maximal heat production, primarily due to shivering, lasts only a few hours because of fatigue and glycogen depletion.

Shivering thermogenesis increases the basal metabolic rate up to five times, markedly increasing oxygen consumption. Shivering begins at normal core temperature when the skin is cooled. Shivering intensity is modulated by the posterior hypothalamus and the spinal cord. The preoptic anterior hypothalamus orchestrates nonshivering heat conservation and dissipation.

Heat loss occurs by radiation, conduction, convection, respiration, and evaporation. In a normally clothed resting human at room temperature, 55% to 65% of heat loss is by radiation. Heat loss by radiation is greatest when a person is spread out unclothed and lowest when a person is curled up and insulated. Radiative heat loss depends on the temperature gradient between the environment and exposed body surface area. Conduction normally accounts for 2% to 3% of the heat loss, but increases up to five times in wet clothing. Conduction and convection in cold water can increase heat loss by a factor of 25.

Individuals with greater amounts of subcutaneous fat lose heat more slowly than thin people. Convective losses increase with shivering. Respiration and evaporation account for heat lost in the heating of inspired air and by insensible evaporation from the skin and lungs.

Cutaneous and respiratory heat loss are markedly influenced by the ambient temperature, air motion, and relative humidity. Greater losses occur in a cool, dry, windy environment. When there is no sweating, most heat loss is through radiation and convection. Convective losses are significant in immersion-induced hypothermia. Children cool faster than adults because they have higher ratios of surface area to mass. Chronic cold exposure may result in thermal acclimation (Fig. 132.1).

When the core temperature ranges from 37°C to 30°C (98.6°F–86°F), vasodilatation, shivering, and nonshivering basal and endocrinologic thermogenesis generate heat. From 30°C to 24°C (86°F–75.2°F), a progressive depression of the basal metabolic rate occurs without shivering. At temperatures below 24°C (75.2°F), autonomic and endocrinologic mechanisms for heat conservation become inactive.

**Pathophysiology**

The physiologic characteristics of hypothermia are described in Table 132.1.

**Cardiovascular System**

Initial tachycardia is followed by progressive bradycardia. The pulse decreases by 50% at 28°C (82.4°F). If the degree of tachycardia is inconsistent with the core temperature, associated conditions such as hypoglycemia, drug ingestion, and hypovolemia should be considered.

The bradycardia of hypothermia results from decreased spontaneous depolarization of cardiac pacemaker cells and is refractory to atropine. The electrocardiographic features of hypothermia include the Osborn (J) wave seen at the junction of the QRS complex and ST segment with core temperatures below 32°C (89.6°F; Fig. 132.2). J waves are neither unique to hypothermia nor of any prognostic value. J waves are normally upright in aVL, aVF, and the left precordial leads. J waves can also be seen during local cardiac ischemia, with sepsis or CNS lesions, and
hypocalcemia. J waves may resemble myocardial injury current and may not be recognized by computer interpretations. This can result in mistaken thrombolyis, which could exacerbate preexistent coagulopathies. Hypothermia can also cause electrocardiographic changes that mimic Brugada syndrome.

Atrial and ventricular dysrhythmias are common in moderate or severe hypothermia. Because the conduction system is more sensitive to the cold than the myocardium, cardiac cycle prolongation occurs. As hypothermia worsens, the PR interval, then the QRS interval, and finally the QTc interval become prolonged. Even in the absence of shivering, increased muscle tone may obscure P waves or produce artifacts. Atrial fibrillation is common when the core temperature is below 32°C (89.6°F). Sinus atrial or junctional rhythms also occur. Atrial fibrillation usually converts spontaneously during rewarming, but mesenteric embolization is a hazard.

Ventricular fibrillation (VF) may be caused by tissue hypoxia, physical jostling, electrophysiologic or acid-base disturbances, and autonomic dysfunction. Asystole and VF can occur spontaneously when the core temperature falls below 25°C (77°F), but vital signs may persist well below 24°C (75.2°F).

The term core temperature afterdrop refers to a decrease in an individual’s core temperature after removal from the cold. Temperature equilibration by conduction contributes to afterdrop, but countercurrent cooling of blood perfusing cold tissues results in a greater decrease in the core temperature.

Active external rewarming of the extremities abolishes peripheral vasoconstriction and reverses arteriovenous shunting. In one human experiment, cooling followed by immersion in a warm bath produced a 30% fall in mean arterial pressure, with a 50% decrease in peripheral vascular resistance.

Core temperature afterdrop is a clinically relevant consideration in the treatment of patients with a large temperature gradient between the core and periphery. Large afterdrops can occur in severely hypothermic patients if frostbitten extremities are thawed before the core is rewarmed.

Central Nervous System

Hypothermia progressively depresses the CNS. Significant alteration of the brain’s electrical activity begins below 33.5°C (92.3°F). The electroencephalogram silences at 19°C to 20°C (66.2°F–68°F). Cerebral autoregulation is maintained with an increase in vascular resistance until 25°C (77°F). In cases of severe hypothermia, there is a redistribution of blood flow to the brain. Like the heart, the brain has a critical period of tolerance to hypothermia.

Renal System

Exposure to cold induces a diuresis, regardless of the state of hydration. The kidneys excrete a large amount of dilute urine that is essentially glomerular filtrate and does not clear nitrogenous

**Fig. 132.1.** Physiology of cold exposure.
subcutaneous fat. Severe malnutrition with wasting contributes to heat loss. Kwashiorkor is less of a risk due to the insulating effect of hypoproteinemic edema.

Neonates are at particular risk of hypothermia due to large surface area-to-mass ratio, relatively deficient subcutaneous tissue, and inefficient shivering. Neonates lack behavioral defense mechanisms. Acute neonatal hypothermia is common after emergency delivery or resuscitation and has also been reported after abandonment of infants. Hypothermic neonates are lethargic, fail to thrive, and have a weak cry. Many have paradoxical rosy cheeks. Late-onset hypothermia, which occurs after 72 hours of life, is often due to septicemia. Hypothermia can occur in shaken baby syndrome and may be a factor in some cases of sudden infant death syndrome.

Most older adults are capable of normal thermoregulation, but conditions such as immobility and systemic disease may interfere with heat production and conservation. Geriatric autonomic dysfunction may cause an inability to sense cold, abnormal adaptive behavioral responses, and decreased peripheral blood flow.

Increased Heat Loss. Patients with erythoderma, such as psoriasis, exfoliative dermatitis, ichthyosis, eczema, and burns, can have increased peripheral blood flow. Iatrogenic causes of heat loss include exposure during resuscitation, cold or room temperature infusions, overcooling of patients with heat stroke, and overzealous burn treatment.

Ethanol is metabolized slowly in hypothermia and interacts with thermoregulatory neurotransmitters. Ethanol may directly suppress the activity of the posterior hypothalamus and mammary bodies. Cutaneous heat loss increases through vasodilatation. Shivering thermogenesis is decreased. Ethanol is the most common cause of excessive heat loss in urban settings. Aging is associated with an increased sensitivity to the hypothermic waste products. Severe hypothermia causes relative central hypervolemia due to peripheral vasoconstriction. Cold diuresis may act as a volume regulator to diminish the capacitance vessel overload. Cold water immersion can further increase urinary output by 3.5 times. Ethanol also increases urinary output.

**Respiratory System**

Hypothermia initially stimulates respiration, followed by a progressive decrease in the respiratory minute volume. Carbon dioxide production decreases 50% with an 8°C (46.4°F) decrease in temperature. Stimuli for respiratory control are altered in severe hypothermia. Carbon dioxide retention with respiratory acidosis can occur. Hypercapnia increases core temperature cooling during snow burial. Other pathophysiologic factors that adversely affect the respiratory system include viscous bronchorrhea, decreased ciliary motility, and noncardiogenic pulmonary edema.

**Predisposing Factors**

Factors that predispose to hypothermia include decreased heat production, increased heat loss, and impaired thermoregulation (Box 132.1). Hypothermia can occur, even in warm conditions. Decreased heat production may be due to endocrine dysfunction, such as hypopituitarism, hypoadrenalism, or myxedema. Myxedema coma is several times more common in women, up to 80% of whom are hypothermic. Hypothyroidism is often occult, with no history of lassitude, dry skin, arthralgias, or cold intolerance.

Hypoglycemia can predispose to hypothermia. Another cause of decreased heat production is malnutrition, with a decrease in subcutaneous fat. Severe malnutrition with wasting contributes to heat loss. Kwashiorkor is less of a risk due to the insulating effect of hypoproteinemic edema.

Neonates are at particular risk of hypothermia due to large surface area-to-mass ratio, relatively deficient subcutaneous tissue, and inefficient shivering. Neonates lack behavioral defense mechanisms. Acute neonatal hypothermia is common after emergency delivery or resuscitation and has also been reported after abandonment of infants. Hypothermic neonates are lethargic, fail to thrive, and have a weak cry. Many have paradoxical rosy cheeks. Late-onset hypothermia, which occurs after 72 hours of life, is often due to septicemia. Hypothermia can occur in shaken baby syndrome and may be a factor in some cases of sudden infant death syndrome.

Most older adults are capable of normal thermoregulation, but conditions such as immobility and systemic disease may interfere with heat production and conservation. Geriatric autonomic dysfunction may cause an inability to sense cold, abnormal adaptive behavioral responses, and decreased peripheral blood flow.

actions of ethanol. Intoxicated persons may be incapable of adaptive behavior to avoid cold. Hypothermic alcoholic ketoacidosis also occurs.

**Impaired Thermoregulation.** Thermoregulation can be impaired centrally, peripherally, or metabolically. Skull fractures, particularly basilar fractures, and chronic subdural hematomas are associated with central impairment. Other causes include strokes, neoplasms, anorexia nervosa, and Hodgkin’s and Parkinson’s diseases. The final common pathway in these disorders may be centrally mediated vasodilation. Cerebellar lesions produce choreiform inefficient shivering.

In therapeutic or toxic doses, antidepressants, mood stabilizers, antipsychotics, anxiolytics, and general anesthetics interfere with thermoregulation by impairing centrally mediated vasoconstriction. Other overdoses, including by organophosphates, heroin, sedative hypnotics, barbiturates, and carbon monoxide, predispose to hypothermia.

Peripheral thermoregulatory failure occurs in neurogenic shock after acute spinal cord transection. In cord injury, disruption of the autonomic nervous system eliminates vasoconstriction. The patient effectively becomes poikilothermic and can rapidly become hypothermic. Neuropathies and diabetes are also peripheral causes of heat loss. Abnormal plasma osmolality may cause hypothalamic dysfunction in uremia, lactic acidosis, diabetic ketoacidosis, and hypoglycemia.

**Traumatic Factors**  
After trauma, hypotension and hypovolemia jeopardize thermosability. In patients with major injuries, there is a fall in skin and core temperatures, without shivering. Thermoregulation is impaired, and heat production decreases.

Hypothermia may exacerbate blood loss by inducing coagulopathy due to impaired activity of coagulation factors and enhanced plasma fibrinolytic activity, with decreased function and sequestration of platelets. Hypothermia in trauma is a risk factor for multiorgan dysfunction.

Traumatic injuries may be missed if hypotension or neurologic findings such as areflexia or paralysis are misattributed to hypothermia. Major risk factors for hypothermia in trauma patients include extremes of age, severe injury, intoxication, large transfusion requirements, and prolonged field, emergency department (ED), and operating room times.

Hypothermia can protect the brain from ischemia only when induced before shock develops. This reduces adenosine triphosphate (ATP) use while ATP stores are nearly normal. In trauma patients, ATP stores are already depleted.
CLINICAL FEATURES

Appreciation of subtle presentations facilitates the early diagnosis of mild to moderate hypothermia. Vague symptoms include hunger, nausea, confusion, dizziness, chills, pruritus, and dyspnea (Box 132.2). During outdoor activities, individuals may simply become uncooperative, uncoordinated, moody, or apathetic. Indoors, older patients may exhibit confusion or become less communicative and may display lassitude or a peculiar flat affect. Progression of mental deterioration or motor skill impairment may mimic dementia. Symptoms such as slurred speech and ataxia may resemble symptoms of stroke or intoxication. Some older adults have a decreased ability to sense cold and fail to take adaptive action.

Paradoxical undressing has been widely reported in hypothermic patients. This last preterminal effort may be related to the peripheral vasoconstrictive changes of hypothermia. Patients have been mistaken for victims of sexual assault or as having a psychiatric disorder.

In urban settings, hypothermia is usually associated with alcohol consumption or underlying illness. Other common causes include stroke, overdose, psychiatric emergency, and major trauma.

Neurologic manifestations vary widely. A progressive decrease in the level of consciousness is usually proportional to the degree of hypothermia. Some patients, however, continue to be verbally responsive and display intact reflexes at 27°C to 25°C (80.6°F–77°F).

Eye movement abnormalities and extensor plantar responses do not correlate directly with the degree of hypothermia. Cranial nerve signs may be seen with bulbar damage from central pontine myelinolysis. Above 22°C (71.6°F), it should be assumed that

nonreactive dilated pupils reflect inadequate tissue perfusion rather than hypothermia.

Neuromuscular examination may reveal stiff posture, pseudo-rigor mortis, or opisthotonos. Reflexes are usually hyperactive to 32°C (89.6°F) and then become hypoactive, disappearing around 26°C (78.8°F). Cremasteric reflexes are absent because the testicles are already retracted. The plantar response usually remains flexor until 26°C (78.8°F). The knee jerk is the last reflex to disappear and the first to reappear with rewarming. Diagnosis of CNS disorders, including spinal cord lesions, may be obscured by hypothermia.

From 30°C to 26°C (86°F–78.8°F), both contraction and relaxation phases of the reflexes are equally prolonged. If intact, the ankle jerk is helpful to diagnose hypothermic myxedema. Myxedema characteristically prolongs the relaxation phase more than the contraction phase.

Psychiatric disorders do not improve when the patient is cold. Mental status alterations include anxiety, perseveration, neurosis, and psychosis. Individuals who are functional in warm conditions may decompensate in colder weather. Hypothermia-induced psychiatric presentations and suicide attempts are commonly misdiagnosed.

**DIAGNOSTIC CONSIDERATIONS**

**Differential Diagnosis**

The differential diagnosis of hypothermia is broad and includes hypothyroidism, hypopituitarism, diabetes, hypoglycemia, malnutrition, intracranial and spinal cord injuries, and sedative-hypnotic and alcohol intoxication (see Box 132.1). Hypothermia is also common in patients with Wernicke’s encephalopathy. Hypothermia can mask the usual clinical triad of ophthalmoplegia, confusion, and truncal ataxia. Intravenous thiamine can be diagnostic and therapeutic.

Hypothermia occurs in conjunction with infections, most commonly overwhelming gram-negative sepsis, pneumonia, meningitis, and encephalitis. Other infections that can lead to hypothermia include bacterial endocarditis, brucellosis, malaria, syphilis, typhoid, miliary tuberculosis, and trypanosomiasis.

Medical conditions associated with hypothermia include carcinoma, pancreatitis, peritonitis, and cerebrovascular disease. Low cardiac output resulting from myocardial infarction can induce hypothermia. Fetal and maternal bradycardia and hypothermia may result from magnesium sulfate infusion during preterm labor. Delayed recovery from neuromuscular blockade may result from hypothermia.

Although many conditions can cause or be associated with accidental hypothermia, as noted, there is no true differential diagnosis of accidental hypothermia once the diagnosis has been established by core temperature measurement.

**Diagnostic Testing**

Except in mild cases of hypothermia, initial laboratory evaluation should include glucose level, complete blood cell count, comprehensive metabolic panel, serum lipase level, and coagulation studies. Blood urea nitrogen and creatinine levels should be checked because renal failure may occur after rewarming in patients with chronic hypothermia. Arterial or venous blood gases, if obtained, should not be temperature-corrected.

A serum ethanol level and urine toxicology screen may be helpful based on history or when a depressed level of consciousness is inconsistent with the degree of hypothermia. Thyroid function studies, cardiac markers, and serum cortisol levels may also be indicated.

**Acid-Base Balance**

Blood gas analyzers warm blood to 37°C (98.6°F), increasing the partial pressure of dissolved gases. This results in arterial blood gases with higher oxygen and carbon dioxide and lower pH than in vivo values. Attempting to maintain a corrected pH at 7.4 and arterial partial pressure of carbon dioxide (PaCO₂) at 40 mm Hg during hypothermia depresses cerebral and coronary blood flow and cardiac output and increases the incidence of VF. The ideal acid-base goal is an uncorrected pH of 7.4 and PaCO₂ of 40 mm Hg.

Cold blood buffers poorly; in normothermia, pH decreases by 0.08 unit for every 10-mm Hg increase in PaCO₂. At 28°C (82.4°F), the decrease in pH doubles. Because the neutral point of water at 37°C (98.6°F) is a pH of 6.8, the normal 0.6-unit pH offset between blood and intracellular water should be maintained at all temperatures (Fig. 132.3). Intracellular electrochemical neutrality ensures optimal enzymatic function at all temperatures. Relative alkalinity affords myocardial protection and improves the heart’s electrical stability.

**Hematologic Evaluation**

The hematocrit can be deceptively high due to decreased plasma volume. The hematocrit increases 2% for every 1°C (3.3°F) fall in temperature. A low-normal hematocrit level in a moderately to severely hypothermic patient should suggest acute or chronic blood loss.

Spleenic, hepatic, and splanchnic sequestration in hypothermia decreases leukocyte and platelet counts. A normal white blood cell count never excludes infection, especially if the patient is debilitated, alcoholic, myxedematous, or at either age extreme.

Frequent evaluation of serum electrolyte levels during rewarming is essential. There are no safe predictors of values or trends. Changes occur in membrane permeability and in the sodium-potassium pump. The patient’s preexisting physiologic status, severity and chronicity of hypothermia, and method of rewarming alter the serum electrolyte values.

The plasma potassium level is independent of hypothermia. Hyperkalemia can be associated with metabolic acidosis, rhabdomyolysis, or renal failure. Hypothermia enhances the cardiac toxicity of hyperkalemia and obscures premonitory electrocardiographic changes. Hypokalemia is most common with chronic
Hypothermia. It results from potassium entering muscle, rather than potassium diuresis. A decline in the serum potassium level despite a decreasing serum pH is caused by intracellular pH fluxes greater than extracellular pH fluxes.

Conditions associated with hypokalemia include preexisting diabetic ketoacidosis, hypopituitarism, inappropriate secretion of antidiuretic hormone, previous diuretic therapy, and alcoholism. If the potassium level is less than 3 mEq/L, supplementation should be given during rewarming.

Blood urea nitrogen and creatinine levels are elevated with preexisting renal disease or decreased clearance. Because of hypothermic fluid shifts, hematocrit and blood urea nitrogen levels are poor indicators of actual fluid status.

The blood glucose level may provide a subtle clue to the type of hypothermia. Acute hypothermia initially elevates the blood glucose level by catecholamine-induced glycosgenolysis, diminished insulin release, and inhibition of cellular membrane glucose carrier systems. Subacute and chronic hypothermia produce glycogen depletion, leading to hypoglycemia. Hypoglycemia can also develop during rewarming in acute hypothermia. Symptoms of hypoglycemia can be masked by hypothermia. A cold-induced renal glycosuria neither implies hyperglycemia nor guarantees normoglycemia.

When hyperglycemia persists during rewarming, one should suspect hemorrhagic pancreatitis or diabetic ketoacidosis. Patients with diabetic ketoacidosis should be actively rewarmed past 30°C (86°F) because insulin is ineffective below that temperature. Correction of hypoglycemia corrects the level of consciousness only to that corresponding to the level of hypothermia.

Severe hypothermia also causes serum enzyme level elevation because of the ultrastructural cellular damage. Rhabdomyolysis is commonly associated with cold exposure. Ischemic pancreatic necrosis may result from the microcirculatory shock of hypothermia. Decreased pancreatic blood flow then activates proteolytic enzymes, increasing the serum lipase level.

Hypothermic Coagulation

A physiologic hypercoagulable state occurs with hypothermia and can be associated with a disseminated intravascular coagulation (DIC)—type syndrome. The cause may be catecholamine or steroid release, circulatory collapse, or release of tissue thromboplastin from cold, ischemic tissue.

Coagulopathies also occur because the enzymatic activity of the activated clotting factors is depressed by the cold. Clotting prolongation is proportional to the number of steps in the cascade. Because kinetic tests of coagulation are performed in the laboratory at 37°C (98.6°F), there is a disparity between in vivo, clinically evident coagulopathy and deceptively normal prothrombin times reported by the laboratory. The only effective treatment is rewarming, not administration of clotting factors.

Leukopenia and thrombocytopenia usually reverse with rewarming. Clinically significant coagulopathies can still occur, particularly in association with trauma. Cold-induced thromboctopenia may be from direct bone marrow suppression or splenic and hepatic sequestration. Platelet thrombocytopenia B2 production is also temperature-dependent. Thrombocytopenia is more common at both age extremes.

Elevated viscosity seen in hypothermia may be exacerbated in patients with cryoglobulinemia or cryofibrinogenemia, especially in older patients. Cryofibrinogen, a cold-precipitated fibrinogen, is associated with collagen vascular diseases, carcinomas, and coliform sepsis. Cold hemagglutination from cold agglutinins produces hemolysis or agglutination with thrombosis, which might explain the increase in coronary and cerebral thromboses in winter.

Imaging

If the patient is not alert and there is suspicion of trauma, standard trauma imaging is indicated, including a focused assessment with sonography in trauma (FAST) bedside ultrasound examination and computed tomography (CT) scan of the head. CT scanning of the abdomen and pelvis may show pancreatic calcifications, unsuspected pneumoperitoneum, small bowel dilation from hypothermia-induced mesenteric vascular occlusion, or colonic dilation associated with myxedema coma.

MANAGEMENT

General Measures

Patients who are cold, stiff, and cyanotic, with fixed pupils, inaudible heart tones, and no visible thoracic excursions, can still be successfully resuscitated. Unexpectedly, some patients still recover completely in the morgue.

Pertinent history includes information about preexisting cardiac, pulmonary, neurologic, or endocrine disease. The duration of exposure, circumstances of discovery, associated injuries, and predisposing conditions should be documented. Initial management should emphasize prevention of further heat loss. Specific goals of prehospital care include prevention of further heat loss with insulation, avoidance of afterdrop, gentle handling, and transporting in a horizontal position. Patients should be actively rewarmed in the field, if possible.

A patient who is unresponsive and not shivering should be treated for severe hypothermia. At core temperatures below 32°C (89.6°F), one should expect an irritable myocardium, temperature gradient between core and periphery, and relative hypovolemia.

In the ED, hypothermia should be confirmed and monitored with continuous core temperature evaluation. Clinically, the rectal temperature is most widely used. However, it lags behind core temperature changes and is influenced by lower extremity temperatures and probe placement. The probe should be inserted to 15 cm and not placed into cold feces.

Epitympanic temperature equilibrates rapidly with core temperature and is closest to the hypothalamic temperature. Most epitympanic probes are not suitable for field use. Infrared thermography ( tympanic temperature) is too unreliable to be used, except to exclude hypothermia. If the airway is protected, an esophageal probe placed in the lower third of the esophagus is the ideal method for continuous core temperature monitoring. If the probe is placed higher, the reading can be falsely elevated by inhalation of heated oxygen.

Hand-held Doppler may be useful to establish the presence of a spontaneous pulse. Bedside cardiac ultrasonography should precede chest compressions. Pulse oximetry is usually unreliable in hypothermia with peripheral vasoconstriction. It is often not possible to obtain an accurate reading. End-tidal carbon dioxide measurements accurately assess tissue perfusion and tracheal tube placement, but only at normal temperatures. Commercially available devices do not function when humidified air is used for airway rewarming.

Endotracheal intubation or placement of a supraglottic airway may be indicated unless the patient has intact protective airway reflexes. Cold depression of ciliary activity allows for the accumulation of secretions with frothy sputum and chest congestion. It may be hard to differentiate between bronchorrhea and pulmonary edema. Nasotracheal intubation can be useful to avoid a surgical airway when cold-induced trismus is present.

Dysrhythmias during intubation are rare. These may be due to failure to preoxygenate, mechanical jostling, acid-base changes, and electrolyte level fluctuations.
A nasogastric tube is indicated after endotracheal intubation. Decreased gastric motility and gastric dilation are common. Physical examination of the abdomen is unreliable because cold can induce rectus muscle rigidity. Many moderately and severely hypothermic patients have decreased or absent bowel sounds. It is important to evaluate the patient for an associated ileus, pancreatitis, or occult trauma.

In moderate and severe hypothermia, indwelling urinary catheters are useful to monitor urine output and help determine the severity of vascular fluid shifts.

Cardiac monitoring should be continuous. Avoid insertion of a central venous pressure catheter tip into the heart, which can precipitate dysrhythmias. Arterial catheters for continuous monitoring of intravascular blood pressure may be helpful in profoundly hypothermic patients. Placement of a pulmonary artery catheter risks perforation of a cold, stiff, pulmonary artery.

**Volume Resuscitation**

Patients with moderate or severe hypothermia are usually volume-depleted. They are prone to thromboembolism resulting from increased viscosity. During rewarming, the total plasma volume is usually high but the circulatory plasma volume is usually low due to increased peripheral vascular resistance.

Rapid volume expansion can be lifesaving, especially in hypothermic neonates. Adult patients with moderate or severe hypothermia should initially receive a 500-mL fluid challenge of heated normal saline. Lactated Ringer’s solution should be avoided because the cold liver metabolizes lactate poorly.

Fluids administered via the intravenous (IV) route should be heated to 40°C to 42°C (104°F–107.6°F). If a commercial fluid or blood warmer is not available, IV fluids can be heated in a standard microwave. The fluid bag should be shaken before administration to avoid hot spots. Rapid central venous administration, which may produce myocardial thermal gradients, should be avoided. Another option in vasoconstricted patients is administration via the intraosseous route.

Countercurrent heat exchangers effectively heat crystalloids and blood from 10°C to 35°C (50°F–95°F). There can be significant conductive heat loss through IV tubing, especially with long lengths of tubing at slow flow rates. It is preferable to administer fluids as boluses to effect rather than as drips.

Normally, hypothermia increases natriuresis. Preexisting gastrointestinal losses or previous diuretic treatment can also contribute to sodium loss. Patients with a normal sodium level and osmolality may have preexisting sodium overload as a result of cirrhosis, nephrosis, or congestive heart failure. However, most patients will be free water–depleted, elevating the sodium level and osmolality.

Hemoconcentration due to decreased plasma volume, fluid shifts, and increased vascular permeability usually is present. Hemodilution can occur from parenteral crystalloid administration, but a low hematocrit can also result from acute hemorrhage or preexisting anemia.

**Advanced Life Support**

During hypothermic cardiac arrest, cardiac output and cerebral and myocardial blood flows are much less than those during normothermic closed chest compressions. Metabolic demands, however, are also less during hypothermia.

Blood flow during cardiopulmonary resuscitation (CPR) in patients with hypothermia differs from flow during normothermia. In normothermia, some flow results from phasic alterations in the intrathoracic pressure rather than from direct cardiac compression. In hypothermia, the heart is a passive conduit, and phasic alterations in the intrathoracic pressure are exerted equally on all cardiac chambers. The mitral valve remains patent during systole, and blood continues to circulate through the left side of the heart. This explains an observation of a thoracotomy in a patient who ultimately survived severe hypothermia: “the heart was found to be hard as stone and it is hardly conceivable how effective external cardiac massage could have been.” There have been many neurologically intact survivors after prolonged closed chest compressions.

Chest wall elasticity and pulmonary compliance are decreased with cold. More force is needed to depress the chest wall sufficiently to generate adequate intrathoracic pressure gradients. Powered thoracic compression devices are useful during prolonged resuscitations pending decisions about extracorporeal rewarming. Apparent rigor mortis and fixed dilated pupils are not reliable criteria for withholding CPR in a hypothermic patient. Dependent lividity has been questioned as a criterion for death in hypothermia, although there have been no reports of survivors. Because intermittent flow may provide adequate support during evacuation, CPR should not be withheld just because continuous compressions cannot be ensured.

Rescuers should initiate CPR in accidental hypothermia unless the do-not-resuscitate status is known, obviously lethal injuries are present, chest wall depression is impossible, signs of life are present, or rescuers are endangered. If possible, verify that there is no spontaneous mechanical cardiac activity with bedside ultrasound before chest compressions are initiated.

**Pharmacologic Treatment**

The efficacy of most medications is temperature-dependent. Protein binding increases during hypothermia. Liver metabolism is decreased. Large doses could be required to achieve a therapeutic response. Toxic levels could develop with rewarming. In severe hypothermia, withhold medications until the patient is warmer, and then leave longer intervals between doses. No medication should be given orally because of the patient’s decreased gastrointestinal motility. Intramuscular medications are also contraindicated because of poor absorption from vasoconstricted sites.

**Cardiovascular Medications**

The effects of hypothermia on the autonomic nervous system are variable. In primates, sympathetic response increases rapidly to cooling from 37°C to 31°C (98.6°F–87.8°F) and then switches off at about 29°C (84.2°F). This suggests that modest catecholamine support might be useful below 29°C (84.2°F).

Pharmacologic manipulation of the pulse and blood pressure should be avoided. Epinephrine and other vasoconstrictors may be dysrhythmogenic and have a minimal effect on the maximally constricted peripheral vasculature. There are no clear indications for vasopressors although, in animal models, the return of spontaneous circulation after induced VF Below 30°C (86°F) is higher after the administration of vasopressors.

Inotropes usually are not necessary to support blood pressure. Inotropic support may be considered in disproportionately hypertensive patients who do not maintain a mean arterial pressure of 60 mm Hg in response to volume replacement and rewarming.

Atrial dysrhythmias are common below 32°C (89.6°F), associated with a slow ventricular response. Atrial fibrillation is common but self-limited. It usually converts spontaneously during rewarming. Beta blockers and calcium channel blockers are contraindicated unless there is a rapid ventricular response.

Preexisting, chronic, premature ventricular contractions can be suppressed during hypothermia and recur during rewarming. Most hypothermia-induced dysrhythmias convert spontaneously during rewarming. Asystole that develops during rewarming is not as ominous as asystole in normothermic patients. For
VF, defibrillation should be attempted at the usual energy. Successful defibrillation has been reported at 20°C (68°F) but attempted defibrillation is often unsuccessful until the core temperature is above 30°C (86°F). If a defibrillation attempt is unsuccessful, active rewarming should be initiated while continuing CPR. Defibrillation attempts can be given occasionally during rewarming. Once the core temperature is above 30°C (86°F), further attempts can be made.7

The ideal approach to ventricular dysrhythmias in the hypothermic patient has not been well studied. Lidocaine and propranolol have minimal hemodynamic effects during hypothermia. Their efficacy in the treatment of ventricular dysrhythmias appears limited. In a canine model of severe hypothermic VF, neither amiodarone nor bretylium was effective. Human chemical defibrillations with bretylium tosylate in cases of severe hypothermia have been reported. There was a case report in which recurrent VF was controlled by isoproterenol.12 Amiodarone can cause torsades de pointes by QT prolongation. The safety of amiodarone during accidental and induced hypothermia is not known.

In hypothermia, at least one Group 1 antidysrhythmic agent, procainamide, increases the incidence of VF. Another drug in the same group, quinidine, can prevent VF during induced profound hypothermia and during cardiac manipulation at 25°C to 30°C (77°F–86°F).

Transvenous cardiac pacing is hazardous for bradydysrhythmias in hypothermia. External pacing may be worth trying in the rare setting of profoundly disproportionate bradycardia. Transcutaneous pacing has been used to facilitate continuous arteriovenous rewarming in perfusing patients by raising the systolic blood pressure above 60 mm Hg. Other active rewarming techniques do not require specific pressure gradients.

**Antibiotics**

Hypothermia compromises host defenses and predisposes to infection. In hypothermia, the usual signs of infection, including fever, are absent. Shaking chills from sepsis may be mistaken for shivering. If a patient’s mental status remains altered, despite rewarming, CNS injury or infection should be suspected.

In hypothermic children younger than 3 months, empirical antibiotics are indicated after cultures have been obtained. There are no reliable clinical or laboratory indicators of infection, but bradycardia, anemia, uremia, and high serum glucose levels, as well as leukocyte abnormalities, are common clues. The role of empirical antibiotics in adults is less clear. Although gram-negative septicemia may cause hypothermia, coexistent infections from gram-positive cocci, Enterobacteriaceae, and oral anaerobes are common.

Older adults with thermoregulatory failure have a high risk of mortality and should be considered septic until proven otherwise. Routine empirical antibiotics do not appear warranted in hypothermic, non–older adults. Antibiotics should be administered if the clinical picture is consistent with septic shock or if there is failure to rewarm. Cellulitis, myositis, bacteriuria, or infiltrate on chest x-rays warrants immediate antimicrobial therapy.

**Failure to Rewarm**

Cold abolishes adrenal responsiveness to adrenocorticotrophic hormone (ACTH). A false diagnosis of decreased adrenal reserve is possible. The increase in ACTH level seen in hypothermic individuals may be a neurogenic or emotional response to the cold.

Acute cold stress initially stimulates cortisol secretion. There may already be a very high level as a result of underlying stress. In clinical series, total serum cortisol levels are commonly elevated; however, the active free fraction is decreased due to increased protein binding. Failure to rewarm may be due to adrenocortical insufficiency or steroid dependence. If either condition is suspected, hydrocortisone, 100 mg IV, should be administered.

Empirical treatment with thyroxine should be reserved for patients thought to have myxedema. Thyroid hormone should be replaced if there is a history of hypothyroidism, suggestive neck scar, or failure to warm. After thyroid function study samples have been drawn, levothyroxine, 250 to 500 μg IV, should be cautiously administered over several minutes. Daily injections of 50 to 100 μg are necessary for 5 to 7 days. Hydrocortisone (100–200 mg) should be added to the first several liters of crystalloid fluid.

The absorption of oral or intramuscular levothyroxine is variable. IV administration has a smooth effect after the onset of action at 6 to 12 hours. This will be manifested by improvement in vital signs and rewarming rate. Half the dose is converted by the peripheral tissues into 1-triiodothyronine (T3). An underlying infection can also compromise thermogenesis. In an urban setting, infection is the leading cause of failure to rewarm and subsequent mortality.

**Rewarming**

No controlled studies comparing rewarming methods in hypothermia have been published. Rigid treatment protocols are not evidence-based. The emergency clinician should choose specific methods on a case by case basis, taking into account availability and clinical experience.

**Passive External Rewarming**

Spontaneous passive external rewarming is noninvasive. It is the treatment of choice for patients with mild hypothermia when active rewarming is not available. The patient should be able to generate sufficient metabolic heat to maintain an acceptable rate of spontaneous rewarming. Older adults are commonly glycogen-depleted, have central hypovolemia, and are not capable of normal cardiovascular or metabolic homeostasis.

The normal processes of heat dissipation are minimized by passive external rewarming. Cessation of evaporation and convection is coupled with insulation against further radiation of heat. This technique simply involves covering the patient with an insulating material in a favorable atmospheric condition. The ambient temperature should exceed 21°C (69.8°F). When the air is stationary, less heat is lost to conduction, convection, and radiation.

Shivering is the most effective thermoregulatory neuromuscular response to cold in humans. Without shivering, endogenously generated metabolic heat is insufficient to raise the core temperature. When the core temperature exceeds 32°C (89.6°F), unless complete glycogen depletion occurs, the major source of heat production is shivering thermogenesis.

Recommended rewarming rates vary between 0.5°C and 2.0°C/hr (32.9°F–35.6°F/hr). The rewarming rate should be rapid enough to avoid prolonged exposure to dysrhythmias. Below 32°C (89.6°F), humans are functionally poikilothermic. Shivering is ineffective below 32°C (89.6°F) and absent below 30°C (86°F).

**Active Rewarming**

Active rewarming is the direct transfer of exogenous heat to the patient. It can be accomplished by external or internal techniques. Active rewarming is useful in mild hypothermia to decrease metabolic requirements of rewarming and improve thermal comfort. In moderate to severe hypothermia, cardiovascular instability and decompensation require prompt elevation of the core temperature while minimizing afterdrop (Box 132.3). Defibrillation...
is rarely successful at temperatures below 28°C (82.4°F). Active rewarming is indicated with strokes and other conditions that impair CNS control of thermoregulation. Active rewarming is also indicated for patients when endogenous thermogenesis is insufficient or when glycogen depletion is present, usually from endocrine causes that include hypopituitarism, adrenal insufficiency, hypothyroidism, and Wernicke’s encephalopathy. Active rewarming is recommended in diabetic ketoacidosis because the core temperature must be elevated above 30°C (86°F) before insulin becomes effective.

Pharmacologically induced peripheral vasodilation or acute spinal cord transaction prevents sufficient thermogenesis and requires active rewarming. Patients with severe hypothermia do not necessarily require invasive extracorporeal rewarming techniques, especially if they have a sustained perfusing rhythm.

Aggressive treatment of hypothermia is indicated in infants. Rapid rewarming is advantageous because it minimizes energy expenditures. Hypothermic neonates have been successfully warmed using minimally invasive methods. A neonate with a core temperature of 14.8°C (58.6°F) receiving CPR made a full neurologic recovery after being warmed by active external rewarming (AER), warmed IV fluids, and heated, humidified ventilator gases.

**Active External Rewarming**

Early concern with AER was sparked after a 1961 study, in which 20 of 23 patients died. Retrospective analysis of clinical series has shown widely varying mortality rates with AER. Various methods conduct heat directly to the skin. Rewarming options include: plumbed garments that circulate warm fluids, hot water bottles, heating pads, forced air warming systems, and radiant sources. Thermal injury to vasoconstricted hyperperfused skin is a potential hazard with local heat application.

Forced air warming systems efficiently transfer heat. They can be used in field conditions or in the ED. These devices circulate hot air through a blanket. The air flows through apertures on the patient’s side, allowing convective transfer of heat. Hypotension and core temperature afterdrop are not seen in forced air warming for accidental hypothermia in the ED. Like all active methods, forced air warming decreases shivering. Forced air warming transfers large amounts of heat while minimizing afterdrop. Other options include the reverse use of endovascular devices intended to produce therapeutic hypothermia in patients after cardiac arrest or thermoregulatory systems that circulate warm water through energy transfer pads.

Arteriovenous anastomosis (AVA) rewarming is a unique, noninvasive, AER technique. Exogenous heat is provided by immersion of distal extremities (upper extremities to the elbows and lower extremities to the knees) in hot (44°C–45°C [111.2°F–113°F]) water. The heat opens the AVAs, which are 1 mm below the epidermal surface in the digits. As a result, there is an increased flow of warmed venous subcutaneous blood returning directly to the heart. The forearms and calves must be included for this technique to be effective. The AVA technique was designed for use on ships and is not practical in most situations. In addition, many patients cannot tolerate the very hot water. Burns of vasoconstricted skin are a potential hazard.

Previously healthy patients with acute hypothermia are optimal candidates for AER. They have minimal dehydration and pathophysiologic circulatory changes. If AER is used, and the extremities are vasoconstricted, the heat source should be applied preferentially to the thorax rather than to the extremities. Application of heat to the extremities increases the cardiovascular load by increasing the metabolic requirements of the peripheral musculature. The depressed cardiovascular system may not be able to meet the demands, resulting in cardiovascular collapse.

Combining truncal AER with core rewarming can also be successful. The provision of heated humidified oxygen and warmed IV fluids, in addition to AER, may help prevent hypoxia, metabolic acidosis, core temperature afterdrop, and hypotension. If AER is used to treat moderate or severe hypothermia, it can be combined with one or more active core rewarming techniques.

**Active Core Rewarming.** Many methods achieve active rewarming of the core. These techniques minimize rewarming collapse in patients with a core temperature below 32°C (89.6°F).

- **Airway Rewarming.** Airway rewarming with heated humidified oxygen is a simple and inexpensive method that can be used as an adjunct to other forms of active rewarming in moderate or severe hypothermia. Airway rewarming improves oxygenation, helps avoid afterdrop, stimulates pulmonary cilia, decreases viscosity of pulmonary secretions, and reduces cold-induced bronchospasm. Pulmonary absorption of moisture does not adversely affect surfactant or increase pulmonary congestion.

  The respiratory tract is a limited site for heat exchange, but heated humidified oxygen increases blood oxygen content and temperature in the pulmonary circulation. The myocardium is perfused by warmer oxygenated blood, decreasing intermittent temperature gradients.

  Sufficient minute volume and complete humidification are necessary for maximal heat delivery. Because dry air has low thermal conductivity, ventilation with warm dry air provides negligible heat. Reported increases in rewarming rates from 1°C to 2.5°C/hr (33.8°F–36.5°F/hr) have been reported with heated humidified oxygen. The rates with endotracheal intubation are higher than those with a mask. Positive-pressure ventilation with a mask can be used, but has not been studied.

  Maintenance of sufficient oxygenation is important in moderate to severe hypothermia. In patients on cardiopulmonary bypass cooled to 28°C to 30°C (82.4°F–86°F), the capacity of hemoglobin to unload oxygen to the tissue is less than half that found in normothermic patients. Despite lower metabolic requirements, this decrease in so-called functional hemoglobin, combined with a depressed respiratory minute volume, results in minimal oxygen reserves.

  Some patients maintain a level of spontaneous respiration appropriate to depressed carbon dioxide production. This is not the case in patients with coexisting toxicologic, traumatic, or metabolic depression of the respiratory center.

  The technique for patients with spontaneous respirations requires a heated cascade nebulizer. An immersion heater can be connected to a hose with a warming wire. Because patients with a depressed level of consciousness do not complain of pain, it is essential to check the temperature of the inspired air frequently with an in-line temperature probe. The gas temperature should be maintained at 42°C to 45°C (107.6°F–113°F). Most heater modules require modification to allow the temperature to reach 42°C to 45°C (107.6°F–113°F). Modified heater modules should be labeled to avoid routine use.
Most humidifiers will not exceed 41°C (105.8°F) close to the patient outlet with a 2-m tubing length. Strategies to circumvent the 41°C (105.8°F) ceiling include reduction of tubing length, addition of more heat sources, disabling of the humidifier safety system, and placement of the temperature probe outside the patient circuit. Because of the modest clinical benefit in stable patients, it is probably not worth the effort to circumvent the 41°C (105.8°F) ceiling. The only report of thermal airway injury has been in a patient ventilated by endotracheal tube for 11 hours with an 80°C (176°F) inhalant.

Peritoneal Dialysis. Peritoneal dialysis delivers dialysate at 40°C to 45°C (104°F–113°F). Heat is conducted directly to the intraperitoneal structures through the posterior parietal peritoneum to the solid viscera and through the hemidiaphragms to the heart and lungs. A double-catheter system with suction at the outflow can increase the rate of rewarming to about 6 L/hr. Two liters are infused, retained for 20 minutes, and then aspirated. Rewarming rates average 1°C to 3°C/hr (33.8°F–37.4°F/hr).

An additional benefit of peritoneal dialysis is hepatic rewarming, which reactivates detoxification and conversion enzymes. Serum electrolyte levels should be monitored because peritoneal dialysis can exacerbate preexisting hypokalemia. Peritoneal lavage is useful primarily in severe cases in combination with other rewarming techniques for patients without spontaneous perfusion, but has also been used alone in patients undergoing CPR for whom extracorporeal circulation was thought to be contraindicated due to coagulopathy or was not available.

Heated Irrigation. Heat transfer from irrigation fluids is usually limited due to the minimal surface area available for heat exchange. Gastric or colonic irrigation can cause fluid and electrolyte level fluxes.

Closed thoracic lavage is useful in severe hypothermia. Two large-bore thoracostomy tubes are inserted into one or both hemithoraces. One is inserted anteriorly in the second or third intercostal space at the midclavicular line, the historical classic site for needle thoracostomy. The other is inserted between the fifth and sixth intercostal spaces in the posterior axillary line, the usual site for tube thoracostomy. Normal saline solution is heated to 40°C to 42°C (104°F–107.6°F), infused into the superior tube. The inferior tube is used for drainage. Left-sided tube insertion in perfusing patients risks causing VF. Efficiency of the heat transfer varies with flow rate and dwell times. Pleural adhesions prevent adequate infusion and can result in a tension hydrothorax. Adequate drainage should be ensured to prevent intrathoracic hypertension.

Thoracic lavage is usually reserved for the severely hypothermic patient who does not respond to standard techniques or the patient with another indication for a chest tube. It should be combined with other rewarming modalities in potentially salvageable cardiac arrest patients. However, thoracic lavage has been used successfully in patients requiring CPR when extracorporeal circulation was not available. The rate of rewarming averages 3°C/hr (37.4°F/hr).

Mediastinal irrigation and direct myocardial lavage should be considered only in patients without spontaneous perfusion. The procedure requires a standard left lateral thoracotomy incision. The pericardium is not incised unless an effusion or tamponade is present. The heart is bathed in 1 to 2 L of an isotonic solution heated to 40°C (104°F) for several minutes. The fluid is then removed and the lavage repeated. Internal defibrillation is attempted at intervals of 2°C (35.6°F) after the myocardial temperature exceeds 26°C to 28°C (78.8°F–82.4°F). When a perfusing rhythm is achieved, lavage is continued until the myocardial temperature exceeds 32°C (89.6°F). A median sternotomy approach allows ventricular decompression in addition to direct defibrillation. Open cardiac massage of a cold, rigid, and contracted heart may not generate flow.

Endovascular Rewarming. Another active core rewarming option uses endovascular warming devices that are intended for therapeutic cooling and subsequent rewarming of comatose, resuscitated, cardiac arrest patients. These systems involve femoral vein catheterization with a closed-loop catheter that has a thermostat at the tip. If the core temperature is below 30°C (86°F), the fail-safe feature on the console must be circumvented to allow rewarming.

Diathermy. Truncal diathermy involves the conversion of energy waves into heat. Large amounts of heat can be delivered to deep tissues with ultrasonic and low-frequency microwave irradiation. Frostbite, burns, significant edema, and the presence of all types of metallic implants and pacemakers are contraindications. In spite of successes in piglets, infants, and a few adults, diathermy is still experimental.

Extracorporeal Blood Rewarming. The four common extracorporeal techniques to warm blood are venovenous rewarming, hemodialysis, continuous arteriovenous rewarming, and extracorporeal circulation—cardiopulmonary bypass (CPB) and extracorporeal membrane oxygenation (ECMO; Table 132.2).

In venovenous rewarming, blood is removed, ideally by a large peripheral venous catheter, heated to 40°C (104°F) and returned through a second venous catheter. Flow rates are 150 to 400 mL/min. The circuit is simple and efficient. There is no oxygenator, and the system does not provide circulatory support. Volume infusion is the only option to augment inadequate cardiac output.

Standard hemodialysis is a widely available and practical rewarming technique. It is portable and efficient and can also be used to treat electrolyte abnormalities, renal failure, or intoxication with a dialyzable substance.

Continuous arteriovenous rewarming is an option if the blood pressure is at least 60 mm Hg. This involves the use of percutaneously inserted femoral arterial and contralateral femoral venous catheters. Heparin-bonded tubing circuits obviate the need for systemic anticoagulation. The blood pressure of spontaneously

perfusing, traumatized, hypothermic patients creates a functional arteriovenous fistula by diverting part of the cardiac output out the femoral artery through a commercially available countercurrent heat exchanger. The heated blood is then returned via admixed heated crystalloids through the femoral vein. Continuous arteriovenous rewarming avoids the need for specialized equipment and a perfusionist necessary for cardiopulmonary bypass. The average rate of rewarming is 3°C to 4°C/hr (37.4°F–39.2°F/hr). Because the catheters are 8.5 Fr, the patient should weigh at least 40 kg.

Extracorporeal circulation usually refers to cardiopulmonary bypass or ECMO. In one review, the mean temperature increase was 9.5°C/hr (49.1°F/hr) with CPB. ECMO appears to reduce the risk of intractable cardiorespiratory failure or severe pulmonary edema after rewarming.

The major advantage of extracorporeal circulation in perfusing patients is the preservation of flow if mechanical cardiac activity is lost during rewarming. Other candidates are patients who do not respond to less invasive rewarming techniques, those with completely frozen extremities, and those with rhabdomyolysis accompanied by major electrolyte disturbances. In some European centers, patients without obvious trauma are admitted directly to the operating suite for extracorporeal circulation.

Very rapid rates of rewarming do not necessarily improve survival. Complications of rapid rewarming include DIC, pulmonary edema, hemolysis, and acute tubular necrosis. Extracorporeal circulation can provide cardiovascular support in perfusing but hemodynamically unstable patients.

Extracorporeal rewarming should be considered in hypothermic cardiac arrest patients if there are no contraindications to CPR. A realistic assessment of the risk-benefit ratio for debilitated patients with secondary hypothermia should be made. The lowest temperature in a survivor of induced hypothermia was 9°C (48.2°F). Extracorporeal blood rewarming is unlikely to succeed below 5°C to 10°C (41°F–50°F). Resuscitation should be discontinued if frozen or clotted intravascular contents are identified.

### DISPOSITION

Otherwise healthy patients who have mild primary accidental hypothermia (35°C–32°C [95°F–89.6°F]) usually rewarms easily. They can be safely discharged if a warm environment is available. Patients with mild hypothermia associated with trauma are more difficult to rewarmed and require admission.

Patients with more severe hypothermia (<32°C [89.6°F]) generally require admission to an intensive care setting. These patients should be evaluated for the presence of underlying medical disorders (see Box 132.1). Cardiac monitoring should be considered for patients with persistent toxicologic or metabolic abnormalities and is essential for patients with cardiovascular instability or an inadequate rate of rewarming. Transfer of patients to tertiary care centers is generally not necessary, but severely hypothermic patients may be most easily managed in facilities capable of extracorporeal circulation.

In the past, the treatment dictum was that “no one is dead until they are warm and dead.” Some patients are cold and dead. It would be useful and humane if they could be safely identified. Because human physiologic responses are variable, it is difficult to predict outcome. The type and severity of the underlying or precipitating disease process are the major determinants. Age of the patient is not an independent predictor of mortality.

Trauma, infection, and toxin ingestions unpredictably affect survival. Outcome prediction based on the Glasgow Coma Scale score is unreliable. Significant predictors of poor outcome include asphyxia, prehospital cardiac arrest, low or absent blood pressure, elevated blood urea nitrogen level, and need for endotracheal or nasogastric intubation in the ED. Patients with hypothermic cardiac arrest due to alcohol intoxication may have better neurologic outcomes than patients with hypothermic cardiac arrest from other causes.

The search for a valid triage marker of death continues. Grave prognostic indicators include evidence of intravascular thrombosis (fibrinogen < 50 mg/dL), cell lysis (hyperkalemia > 10–12 mEq/L), and ammonia levels greater than 250 mmol/L.

### KEY CONCEPTS

- Indications for active rather than passive rewarming include cardiovascular instability, temperature below 32°C (89.6°F), poor rate of rewarming, and endocrinologic insufficiency.
- Consider hypoglycemia, hypovolemia, or an overdose if there is a tachycardia disproportionate to the temperature.
- The efficacy of most medications is temperature-dependent. Overmedication to achieve an effect when the patient is cold could cause toxicity during rewarming.
- Laboratory coagulation tests are performed at 37°C (98.6°F). Despite a clinically obvious coagulopathy, the values will be deceptively normal.
- There are no safe predictors of serum electrolyte levels. Hypothermia enhances the cardiac toxicity of hyperkalemia and obscures premonitory electrocardiographic changes.
- Failure to rewarmed despite good technique should suggest infection, endocrine insufficiency, or a futile resuscitation.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Convection is the transfer of heat to a fluid medium and accounts for approximately 3% of heat loss, but can increase up to 25 times in cases involving radiation. Radiation can be minimized by reducing the body surface area. Greater differential results in greater heat loss. Heat loss through radiation depends on the body temperature after prolonged avalanche burial. Ann Emerg Med 60:193–196, 2017.

Hilmo J, Naessheim T, Gilbert M: “Nobody is dead until warm and dead”: prolonged resuscitation is warranted in arrested hypothermic victims also in remote areas—a retrospective study from northern Norway. Resuscitation 85:1204–1211, 2014.

CHAPTER 132: QUESTIONS & ANSWERS

132.1. What type of energy transfer results in the greatest amount of heat loss in a cold environment?
   A. Conduction
   B. Convection
   C. Evaporation
   D. Radiation
   E. Respiration

Answer: D. At an average metabolic rate, radiation accounts for approximately 10% of heat loss but is increased when shivering or in windy conditions. Respiration accounts for approximately 30% of heat loss and is relatively constant. Evaporation (sweating) is the dominant mode of heat loss in hot environments but is negligible in cold environments.

132.2. Emergency medical services (EMS) notifies your emergency department (ED) that an unknown male who was “found down” is being transported. No history is available. Paramedics report that the patient’s pulse is 42 beats/min and blood pressure is difficult to obtain. Spontaneous respirations are present at a rate of 10 breaths/min. The electrocardiogram (ECG) shown here is faxed before the patient’s arrival. What treatment should you administer upon the patient’s arrival?
A. Epinephrine intravenous (IV)
B. Normal saline bolus
C. Pericardiocentesis
D. Synchronized cardioversion
E. Warming the patient

Answer: E. The patient has the classic electrocardiographic finding of hypothermia, the Osborn or J wave. The wave is seen at the junction of the QRS complex and ST segment. Depending on the lead, the wave can be mistaken for ST segment elevation myocardial infarction (STEMI), early repolarization, or simply a widened QRS of unknown cause. The Osborn wave is potentially diagnostic of hypothermia and may be seen at any temperature below 32°C (89.6°F). Epinephrine is potentially indicated in cardiac arrest. Crystalline fluid boluses are generally indicated for any hypotensive patient, especially when hypovolemia is suspected. Pericardiocentesis is only indicated for cardiac tamponade. Synchronized cardioversion is indicated for a variety of tachydysrhythmias.

132.3. Rapid rewarming is the mainstay of treatment for hypothermia. However, rewarming can cause complications. Which of the following complications should be anticipated and prevented when rewarming a hypothermic patient?
A. Cerebral edema
B. Hypokalemia
C. Hyponatremia
D. Hypotension
E. Rhabdomyolysis

Answer: D. When the surface or extremities of a patient are initially warmed, the cold-induced peripheral vasoconstriction is reversed. Rapid peripheral vasodilation can result in up to a 50% decline in peripheral vascular resistance and a 30% decline in mean arterial pressure. The effects are particularly prominent in patients who are also dehydrated—and exposure to cold induces a diuresis—or have frostbitten extremities. The same vasodilation is responsible for core temperature afterdrop, which refers to a further decline in core temperature, partially resulting from the fact that blood is now perfusing cold tissue, and the cold blood is returned to the core. This core afterdrop can also increase the incidence of dysrhythmias. Rhabdomyolysis is commonly seen in hypothermic patients but not specifically when rewarming. None of the other answer choices are commonly seen on rewarming a hypothermic patient.

132.4. A 4-day-old male patient is brought in by parents for poor feeding. His birth history is uneventful; he was full term. He was discharged from the hospital with his mother 2 days ago. Vital signs are within normal limits for his age, with the exception of a temperature of 33.5°C (92.3°F). Physical examination reveals a drowsy but arousable boy. Otherwise, the physical examination is unremarkable. What is the most likely diagnosis?
A. Congenital heart disease
B. Hypernatremia
C. Hyponatremia
D. Sepsis
E. Still’s disease

Answer: D. Neonates have poor thermoregulatory mechanisms, and neonatal hypothermia is relatively common after precipitous delivery. However, with proper care, the hypothermia resolves and does not cause long-term problems. Hypothermia 72 hours after birth is frequently caused by sepsis. A full septic evaluation is indicated in this case. Neonatal hypothermia is also associated with hypoglycemia and child neglect or abuse. Poor feeding and dehydration can result in hyperthermia, whereas dilution of infant formula can result in hyponatremia. Neither should result in hypothermia. Congenital heart disease frequently presents with distress during feedings but, similarly, should not result
in hypothermia. Still’s disease is a rare rheumatologic disease associated with fever, arthralgia, and rash.

132.5. Which substance directly interferes with thermoregulatory neurotransmitters, may directly damage the thermoregulatory centers of the brain, and therefore predisposes to hypothermia?

A. Cocaine  
B. Ethanol  
C. Nicotine  
D. Phencyclidine  
E. Tetrahydrocannabinol (THC)

**Answer:** B. Ethanol interacts with all thermoregulatory neurotransmitters and may damage the posterior hypothalamus and mammillary bodies. It also causes vasodilation and decreased shivering, as well as inhibiting normal adaptive behavior to cold. In urban settings, most cases of hypothermia are associated with ethanol. Cocaine and phencyclidine are stimulants and may cause hyperthermia. Nicotine and THC do not directly interact with the thermoregulatory centers.

132.6. A 47-year-old man is brought to the ED after being “found down.” No further history is available. His vital signs are normal with the exception of temperature, which is 31°C (87.8°F). He is lethargic and only responds to painful stimuli by withdrawing. He has several scalp lacerations that are bleeding profusely. You appropriately intubate this patient to secure his airway. Despite direct pressure, injection of epinephrine, and all other techniques at your disposal, the patient continues to bleed from his scalp lacerations. You also notice multiple new areas or bruising and bleeds on various parts of the patient. What should be done to reverse the coagulopathy most rapidly?

A. Intranasal desmopressin  
B. IV vitamin K  
C. Transfusion of fresh-frozen plasma (FFP)  
D. Transfusion of platelets  
E. Warming the patient

**Answer:** E. Hypothermia decreases the activity of all clotting factors, which can result in disseminated intravascular coagulation. The only effective treatment is to warm the patient. There is nothing inherently wrong with the patient’s clotting factors; they are merely inactivated by the cold. Any additional clotting factors transfused will also be inactivated by the cold. Hypothermic patients are not thrombocytopenic. Desmopressin enhances the release of von Willebrand factor and factor VIII. Vitamin K is needed for the synthesis of factors II, VII, IX, and X. FFP provides all clotting factors.

132.7. A 30-year-old woman in cardiac arrest is brought to the ED by emergency medical services. She was intubated in the field, and chest compressions have been continuously performed. Her temperature is 25°C (77°F). When placed on the cardiac monitor, she is noted to be in ventricular fibrillation. A defibrillation attempt is made at the appropriate setting, but she remains in ventricular fibrillation. A nurse resumes providing chest compressions and asks for further instructions. What should be done next?

A. IV amiodarone  
B. IV lidocaine  
C. IV procaainamide  
D. Repeating defibrillation  
E. Warming the patient

**Answer:** E. Defibrillation attempts are usually unsuccessful at core temperatures less than 32°C (89.6°F). Chest compressions should continue while the patient is aggressively warmed. Many dysrhythmias spontaneously convert once hypothermia is resolved. If ventricular fibrillation persists at temperatures above 30°C (86°F), another defibrillation attempt should be made. Amiodarone, lidocaine, and procainamide are all antidysrhythmics that could potentially be used in normothermic patients.

132.8. Which of the following is an indication for active rather than passive rewarming in a hypothermic patient?

A. Altered mental status  
B. Associated burns  
C. Associated trauma  
D. Hypoglycemia  
E. Temperature below 32°C (89.6°F)

**Answer:** E. Other indications for active rewarming include cardiovascular instability, poor rate of rewarming, endocrinologic insufficiency, and vasodilation.

132.9. Which of the following patients meets the definition of hypothermia?

A. A patient with a core temperature of less than 35°C (95°F) but with no symptoms  
B. A patient with a core temperature of less than 36°C (96.8°F) with symptoms of hypothermia  
C. A patient with an oral temperature of less than 34°C (93.2°F) but with no symptoms  
D. A patient with an oral temperature of less than 35°C (95°F) with symptoms of hypothermia  
E. A patient with frostbite, regardless of temperature

**Answer:** A. Hypothermia is defined as a core temperature less than 35°C (95°F). Oral temperatures are not reliable. The presence or absence of symptoms can guide management but does not change the definition of hypothermia.

132.10. The search for a valid triage marker of death in the setting of severe hypothermia continues. Which of the following is most suggestive?

A. Ammonia level, 100 mmol  
B. Fibrinogen, >50 mg/dL  
C. Hyperkalemia, 9 mEq/L  
D. International normalized ratio (INR) of 3.2  
E. Low blood urea nitrogen (BUN) level

**Answer:** B. Ominous markers include an ammonia level > 250 mmol/L, hyperkalemia (cell lysis) > 10 to 12 mEq/L, fibrinogen < 50 mg/dL (intravascular thrombosis). The INR is not prognostic because kinetic tests of coagulation are performed in the laboratory at 37°C (98.6°F).
PRINCIPLES

Background

Humans have been plagued by heat illness throughout recorded history, often as the result of military exercises, athletic events, or recreational activities. When environmental heat stress is maximal, strenuous exercise is not required to produce heat illness. Modern military organizations continue to encounter heat illness because of the requirement to train unacclimatized troops with heavy physical exercise. Heat stroke is the third leading cause of death among all US athletes. Of the major sports, football has the greatest number of heat stroke fatalities and a 10 times higher rate for heat illnesses. The health hazards associated with extreme environmental working conditions in many industries have been increasingly recognized worldwide.

Older adults and the poor, who often lack adequate air conditioning and nutrition, and those with preexisting disease are prone to heat illness during environmental extremes. It is estimated that at least 10 times as many heat-aggravated illnesses occur in patients with comorbid conditions, such as coronary artery disease, cerebrovascular disease, and diabetes. In heat wave years in the United States, approximately 10 times as many deaths are reported as during non–heat wave years. Climate models have suggested an increase in frequency and intensity of heat waves in temperate areas of the world. Before the advent of air conditioning, mortality increased three- to fivefold in nursing homes and threefold in the general population during heat waves. Microclimates conducive to heat illness are produced in the interiors of automobiles, military tanks, and tents in the sun, as well as in engine rooms, mines, hot tubs, and saunas. Children are more susceptible to heat stressors because their higher surface area–to–mass ratios allow increased absorption of heat. They also have lower sweat rates per gland.

Anatomy and Physiology

Heat Production

Humans are essentially biochemical furnaces that burn food to fuel with a complex array of metabolic functions. These chemical reactions consume substrate, generate usable energy, and produce byproducts that must be eliminated for continued operation of the system. Water and carbon dioxide are produced and eliminated in large quantities, as are urea, sulfates, phosphates, and other chemical products. These reactions are exothermic and combine to produce a basal metabolic rate that amounts to approximately 100 kcal/hr for a 70-kg person. In the absence of cooling mechanisms, this baseline metabolic activity would result in a 1.1°C (34°F) hourly rise in body temperature.

Heat production can be increased 20-fold by strenuous exertion. Rectal temperatures as high as 42°C (107.6°F) have been recorded in trained marathon runners, without ill effects. Metabolic factors, such as hyperthyroidism and sympathomimetic drug ingestion, can dramatically increase heat production. Environmental heat not only adds to the heat load but also interferes with heat dissipation. The physics of heat transfer as it relates to human physiology involves four mechanisms—conduction, convection, radiation, and evaporation.

Conduction. This is the transfer of heat energy from warmer to cooler objects by direct physical contact. Air is a good insulator; therefore, only approximately 2% of the body heat loss is by conduction. In contrast, the thermal conductivity of water is at least 25 times that of air.

Convection. This is heat loss to air and water vapor molecules circulating around the body. As the ambient temperature rises, the amount of heat dissipated by convection becomes minimal. Once the air temperature exceeds the mean skin temperature, heat is gained by the body. Convective heat loss varies directly with wind velocity. Loose-fitting clothing maximizes convective, and also evaporative, heat loss.

Radiation. This is heat transfer by electromagnetic waves. Although radiation accounts for approximately 65% of heat loss in cool environments, it is a major source of heat gain in hot climates. Up to 300 kcal/hr can be gained from radiation when someone is directly exposed to the hot summer sun.

Evaporation. This is the conversion of a liquid to the gaseous phase. Evaporation of 1 mL of sweat from the skin cools the body by 0.58 kcal. As the ambient temperature rises, evaporation becomes the dominant mechanism of heat loss. Panting mammals such as dogs have an oropharyngeal countercurrent flow mechanism (carotid rete mirabile) that results in selective cooling of the brain. In humans, respiratory and countercurrent mechanisms are minimal sources of heat loss.

Heat Regulation

The regulation of body temperature involves three distinct functions—thermosensors, a central integrative area, and thermoregulatory effectors.

Thermosensors. Temperature-sensitive structures are located peripherally in the skin and centrally in the body. Skin temperature changes, however, correlate poorly with changes in the rate of heat loss. Thermosensitive neurons, located in the preoptic anterior hypothalamus, are activated when the temperature of the blood circulating through that area exceeds a set point (Fig. 133.1).

The skin temperature affects heat loss when a person resting in a warm environment initiates sweating, even though the core temperature remains constant. In contrast, changes in core temperature are more dominant than skin temperature changes in producing heat-dissipating responses.

Central Integrative Area. The central nervous system (CNS) interprets information received from the thermosensors to instruct thermoregulatory effectors properly. The concept of a central thermostat whereby an alteration shifts effector thresholds
in the same direction fits a variety of clinical situations. For example, fever, the circadian rhythm of temperature variation, and the difference in rectal temperature after ovulation can be explained by variation of a thermal set point.

Thermoregulatory Effectors. Sweating and peripheral vasodilation are the major mechanisms whereby heat loss can be accelerated. In a warm environment, evaporation of sweat from the skin is the most important mechanism of heat dissipation. Heat loss from the skin by convection and radiation is maximized by increased skin blood flow to facilitate sweating.

Humans possess apocrine and eccrine sweat glands. Apocrine glands are concentrated in the axillae and produce milky sweat, rich in carbohydrate and protein. They are adrenergically innervated and respond to emotional stress as well as to heat. Most glands producing so-called thermal sweat are eccrine glands. These are cholinergically innervated and distributed over the entire body, with the largest number on the palms and soles. Eccrine sweat is colorless, odorless, and devoid of protein. Individuals exercising in hot environments commonly lose 1 or 2 L/hr of sweat. A loss of up to 4 L/hr is possible with strenuous exercise.

Cooling is best achieved by evaporation from the body surface; sweat that drips from the skin does not cool the body. Each liter of completely evaporated sweat dissipates 580 kcal of heat. The ability of the environment to evaporate sweat is termed atmospheric cooling power and varies primarily with humidity, but also with wind velocity. As humidity approaches 100%, evaporative heat loss ceases.

The vascular response to heat stress is cutaneous vasodilation and compensatory vasoconstriction of the splanchnic and renal beds. These vascular changes are under neurogenic control and allow heat to be dissipated quickly and efficiently, but they place a tremendous burden on the heart. To maintain blood pressure, cardiac output increases dramatically. For this reason, saunas and hot tubs may be dangerous for patients with cardiac disease. Cardiovascular and baroreceptor reflexes also affect skin blood flow. Reduced forearm sweating and vasodilation have been observed in severely dehydrated subjects exercising in a warm environment.

**Acclimatization**

Acclimatization is the constellation of physiologic adaptations that occur in a normal person as the result of repeated exposures to heat stress. Daily exposure to work and heat for 100 min/day results in near-maximal acclimatization within 7 to 14 days. This is characterized by an earlier onset of sweating (at a lower core temperature), increased sweat volume, and lowered sweat sodium concentration. Acclimatization is hastened by modest salt deprivation and delayed by high dietary salt intake.

The cardiovascular system plays a major role in acclimatization and endurance training, largely resulting from an expansion of plasma volume. Heart rate is lower and associated with a higher stroke volume. Other physiologic changes include earlier release of aldosterone, although acclimatized individuals generate lower plasma levels of aldosterone during exercise heat stress. Total body potassium depletion of up to 20% (500 mEq) by the second week of acclimatization can occur as a result of sweat and urine losses, coupled with inadequate repletion.

Although many similarities exist among thermoregulatory responses to heat and exercise, the well-conditioned athlete is not necessarily heat-acclimatized. For heat- and exercise-induced adaptive responses to be maintained, heat exposure needs to continue intermittently, at least on 4-day intervals. Plasma volume decreases considerably within 1 week in the absence of heat stress.

**Pathophysiology**

**Predisposing Factors**

Advanced age, psychiatric conditions, chronic disease, obesity, and certain medications increase the risk for classic heatstroke during periods of high heat and humidity. Adequate fluid intake is essential. Older adults often overdress during hot weather conditions. Heat loss is maximized by light, loose-fitting garments. Exertional heatstroke is most likely to occur in young healthy people involved in strenuous physical activity, especially if they have not acclimatized to environmental factors that overwhelm heat-dissipating mechanisms. Fluid intake is the most critical variable. Dehydration can be minimized by education on work-rest cycles and fluid consumption and through provision of cool flavored fluids.

The goal is to maximize voluntary fluid intake and gastric emptying so that fluid can rapidly enter the small intestine, where it is absorbed. Gastric emptying is accelerated to 25 ml/min by large fluid volumes (500–600 mL) and cool temperatures (10°–15.8°C [50°F–60.4°F]). High osmolality inhibits gastric emptying; osmolality of less than 200 mOsm/L is optimal. Most commercially available electrolyte solutions contain excessive

---

**Fig. 133.1.** Preoptic anterior hypothalamic. (Adapted from Nuclei of the hypothalamus. bhavanajagat.files.wordpress.com/2012/07/nuclei-of-hypothalamus.jpg.)
sugar. Hydration can be monitored by measurement of body weight before and after training or athletic competition. An athlete with a loss of 2% to 3% body weight (1.5–2 L in a 70-kg man) should drink extra fluid and be permitted to compete only when his or her body weight is within 0.5 to 1 kg (1 or 2 pounds) of the starting weight on the previous day. A weight loss of 5% or 6% represents a moderately severe deficit and usually is associated with intense thirst, scanty urine, tachycardia, and increase in rectal temperature of approximately 2°C (35.6°F). These athletes should be restricted to light workouts after hydration until they return to normal weight. A loss of 7% or more of body weight represents severe water depletion; participation in sports should not be permitted until the athlete is evaluated by a physician or sports trainer. Wrestlers frequently fast, restrict food and fluid intake, and exercise vigorously wearing vapor-impermeable clothing to lose weight quickly so that they can compete in a lower weight class.

The administration of salt tablets during strenuous exercise can cause delayed gastric emptying, osmotic fluid shifts into the gut, gastric mucosal damage, and hypernatremic dehydration. A 6-g sodium diet is sufficient for successful adaptation for work in the heat, with sweat losses averaging 7 L/day. Excessively high salt intake in relation to salt losses in sweat during initial heat exposure can impair acclimatization because of the inhibition of aldosterone secretion. Excessive salt ingestion can also exacerbate potassium depletion.

Evaporative cooling can be lost when clothing inhibits air convection and evaporation.1 Loose-fitting clothing or ventilated fishnet jerseys allow efficient evaporation. Light-colored clothing reflects rather than absorbs light. Water evaporated from clothing is much less efficient for body cooling than water evaporated from the skin.

The body’s heat dissipation mechanisms are analogous to the cooling system of an automobile (Fig. 133.2). Coolant (blood) is circulated by a pump (heart) from the hot inner core to a radiator (skin surface cooled by the evaporation of sweat). Temperature is sensed by a thermostat (CNS), which alters coolant flow by a system of pipes, valves, and reservoirs (vasculature). Failure of any of these components can result in overheating.

Effective circulation requires an intact pump and adequate coolant levels. Individuals with cardiac disease or those taking β-adrenergic blocking agents or calcium channel blockers may be unable to increase their cardiac output sufficiently to produce the necessary peripheral vasodilation to dissipate heat. Dehydration caused by gastroenteritis, diuretics, or inadequate fluid intake predisposes to heat illness. Individuals working in the heat seldom voluntarily drink as much fluid as they lose and replace only approximately two-thirds of net water loss (so-called voluntary dehydration). Dehydration alone increases body temperature at rest by increasing the work of the sodium-potassium adenosine triphosphatase pump, which accounts for 25% to 45% of the basal metabolic rate. This is particularly true in cases of hypernatremic dehydration. The pipes and valves of the coolant system may be abnormal in diabetic or older patients with extensive arteriosclerosis.

Radiator function depends on the skin and sweat glands. Occlusive, vapor-impermeable clothing hinders evaporative and convective cooling. Anticholinergic medications and stimulant drugs of abuse interfere with sweating and contribute to heat illness.1 Various skin diseases, including miliaria (prickly heat syndrome), blocking drugs (anticholinergics) or sympathomimetics, are risk factors. Anhidrosis can also be secondary to central or peripheral nervous system disorders.

Increased heat production causing heat illness most often accompanies exercise in a hot humid environment. When heat and humidity are extreme, exertion is not necessary to produce heat-related problems. Several indices help objectify heat strain. These indices can be divided into two categories, heat scales based on meteorologic parameters and heat scales that combine environmental and physiologic parameters.

The wet bulb globe temperature heat index is an excellent meteorologic measure of environmental heat stress (Box 133.1). It includes the effects of temperature, humidity, and radiant thermal energy from the sun. When climatic conditions exceed 25°C (77°F) wet bulb, even healthy people are at high risk during exercise. Above 28°C (82.4°F), exercise and strenuous work should be avoided or limited to extremely short periods.

The heat strain index is widely accepted as an example of an index that includes environmental and physiologic factors. There are several variations and modified heat strain indices, with varying ease of use and accuracy.13

**Fever Versus Hyperthermia**

It is diagnostically and therapeutically important to identify patients suffering from a febrile response rather than heat illness. Fever does not cause primary pathologic or physiologic damage to humans and does not require primary emphasis in the therapeutic regimen, which is directed at the underlying disease state. If temperature-related physiologic changes, such as febrile seizures

**BOX 133.1**

**Wet Bulb Globe Temperature (WBGT)**

\[ \text{WBGT} = 0.7T_a + 0.2T_r + T_s \]

- \( T_a \) = “Natural” wet bulb temperature—the temperature achieved by a thermometer covered with a moistened white wick and left exposed to the ambient environment
- \( T_r \) = Globe temperature—the temperature inside a blackened hollow copper sphere exposed to the ambient environment
- \( T_s \) = Ambient temperature

These measurements can be done manually or calculated automatically with the help of computer algorithms.
and tachycardia, compromise a patient with marginal cardiac reserve, her or his temperature should be artificially regulated with antipyretics. These antipyretics are not effective against heat illness and are not recommended to control environmental hyperthermia.

MINOR HEAT ILLNESS

Prickly Heat

Principles

Prickly heat, also known as miliaria rubra, lichen tropicus, and heat rash, is an acute inflammatory disorder of the skin that occurs in tropical climates. It is the result of the blockage of sweat gland pores by macerated stratum corneum and secondary staphylococcal infection. The acute phase is characterized by vesicles in the malpighian layer of the skin, caused by dilation and rupture of the obstructed sweat gland ducts.

Clinical Features

Clinically, this initially produces intensely pruritic vesicles on an erythematous base. The rash is confined to clothed areas, and the affected area is often completely anhidrotic. During approximately the next week, a keratin plug develops and fills these vesicles, causing a deeper obstruction of the sweat gland duct. The obstructed duct then ruptures a second time, producing a deeper vesicle within the dermis. This is known as the profunda stage, and it can persist for weeks. Profunda vesicles are not pruritic and closely resemble the white papules of piloerection; chronic dermatitis is a common complication (Fig. 133.3).

Differential Diagnosis

Alternatives diagnoses include, contact dermatitis, cellulitis, and allergic reactions.

Diagnostic Testing

Laboratory data is generally not indicated in cases of prickly heat.

Management and Disposition

Chlorhexidine in a light cream or lotion is the antibacterial treatment of choice during the acute phase. Salicylic acid, 1% tid, can be applied to localized affected areas to assist in desquamation, but it should not be used in children or over large areas because of possible salicylate intoxication. For diffuse or pustular rashes, erythromycin can be helpful.

Patients can be discharged home, with a dermatologic follow-up. Prickly heat can be prevented by wearing light, loose-fitting, clean clothing and avoiding situations that produce continuous sweating. The routine use of talcum or baby powder should be avoided.

Heat Cramps

Principles

Heat cramps are brief, intermittent, and often severe muscle cramps occurring typically in muscles that are fatigued by heavy work. Heat cramps appear to be related to a salt deficiency. They usually occur during the first days of work in a hot environment and develop in persons who produce large amounts of thermal sweat and subsequently drink copious amounts of hypotonic fluid.

Clinical Features

Athletes, roofers, steelworkers, coal miners, field workers, and boiler operators are among the most common victims of heat cramps. Heat cramps tend to occur after exercise, when the victim stops working and is relaxing (Box 133.2). In this respect, they differ from the cramps experienced by athletes during exercise, which tend to last for several minutes, are relieved by massage, and resolve spontaneously.

Differential Diagnosis

Heat cramps are occasionally confused with hyperventilation tetany, which can occur during heat exhaustion. Hyperventilation tetany can be distinguished by the presence of carpopedal spasm and paresthesias in the distal extremities and perioral area.

Diagnostic Testing

Heat cramps accompanied by systemic symptoms may be part of salt depletion heat exhaustion. Heat cramp victims exhibit hyponatremia and hypochloremia, so serum electrolyte levels should be measured. Rhabdomyolysis or resultant renal damage is not present with isolated heat cramps.

BOX 133.2

Heat Cramps: Essentials of Diagnosis

| Cramps of most worked muscles |
| Usually occur after exertion |
| Copious sweating during exertion |
| Copious hypotonic fluid replacement during exertion |
| Hyperventilation not present in cool environment |
Management and Disposition

Heat cramps are usually rapidly relieved by salt solutions. Commercially available flavored electrolyte solutions are commonly ingested. Mild cases without concurrent dehydration are treated orally with a 0.1% or 0.2% salt solution (two to four 10-grain salt tablets [56–112 mEq] or ½ to ⅓ teaspoon of table salt dissolved in 1 quart of water), which is the general limit of palatability. Severe cases respond rapidly to an intravenous (IV), isotonic salt solution (0.9% NaCl). Salt tablets are gastric irritants, delay gastric emptying, and are not recommended. Although most patients do not seek medical treatment, most people with heat cramps may be safely discharged after the administration of balanced salt solutions and clinical improvement.

Heat Edema

Principles

It is presumed that hydrostatic pressure and vasodilation of cutaneous vessels, combined with some degree of orthostatic pooling, lead to vascular leak and accumulation of interstitial fluid in the lower extremities. Simultaneously, the aldosterone level increases in response to the heat stress and perceived central volume deficit.

Clinical Features

Swollen feet and ankles are often reported by nonacclimatized individuals, especially older adults, who encounter climatic stresses of tropical and semitropical areas. Such individuals often have no underlying cardiac, hepatic, venous, or lymphatic disease. They commonly have schedules that involve long periods of sitting or standing. The edema is usually minimal, is not accompanied by any significant impairment in function, and often resolves after several days of acclimatization.

Differential Diagnosis

Heat edema should be differentiated from congestive heart failure, liver disease states, lower extremity infections, and deep venous thrombosis.

Diagnostic Testing

Awareness of this clinical presentation prevents overly vigorous diagnostic and therapeutic intervention. A brief diagnostic evaluation to rule out thrombophlebitis, lymphedema, or congestive heart failure is appropriate, but invasive diagnostic techniques are not indicated.

Management and Disposition

Pharmacologic therapy is not indicated, and diuretic therapy is not effective. Simple leg elevation or thigh-high support hose should be used. In most individuals, the problem resolves through adequate acclimatization or with the individual’s return to a temperate climate. Given its benign nature, patients with heat edema can be safely discharged for outpatient management.

Heat Syncope

Principles

Individuals adapt to a hot humid environment by dilation of cutaneous vessels to deliver heat to the body surface. Thus, an increased portion of the intravascular pool is located in the periphery at any given time. Increasing blood flow to compliant cutaneous veins raises skin vascular volume at the expense of thoracic blood volume. Individuals who stand for protracted periods tend to pool blood in the lower extremities. Combined with volume loss and peripheral vasodilation, this pooling can result in inadequate central venous return, a concomitant drop in cardiac output, and cerebral perfusion inadequate to maintain consciousness.

Clinical Features

Heat syncope is a multifactorial disorder that results in a temporary loss of consciousness in the presence of heat exposure. Older adults have a special predilection for this disorder, with a host of concomitant underlying mechanisms.

Differential Diagnosis

The diagnosis of heat syncope requires the appropriate clinical setting and exclusion of other possible causes of syncope, given a patient’s age and underlying medical disorders (see Chapter 12).

Diagnostic Testing

Heat syncope can be precipitated by an underlying metabolic or cardiac disorder, so cardiac monitoring, electrocardiography, and hemoglobin determination are warranted. Other tests are individualized based on clinical suspicion following a thorough history and physical examination (see Chapter 12).

Management and Disposition

The disorder is self-limited, and placing the patient in a horizontal position is generally curative. Older patients with comorbidities may require admission to address cardiac or neurologic causative factors. These individuals are at risk for recurrent heat syncope and should be warned to move often, flex leg muscles repeatedly when standing stationary, avoid protracted standing in hot environments, and assume a sitting or horizontal position when prodromal warning symptoms or signs occur.

MAJOR HEAT ILLNESS

Heat Exhaustion

Principles

Heat exhaustion (heat prostration) is a clinical syndrome characterized by volume depletion that occurs under conditions of heat stress. Two types of heat exhaustion are classically described, water depletion and salt depletion.

Water depletion heat exhaustion results from inadequate fluid replacement by individuals working in a hot environment and incapacitated individuals without free access to water. Those working in the heat seldom drink as much as they lose, and this voluntary dehydration results in progressive hypovolemia. Left untreated, water depletion heat exhaustion will progress to heatstroke because they are a continuum of the same disease.

Salt depletion heat exhaustion takes longer to develop than the water depletion form. It occurs when large volumes of thermal sweat are replaced by water with too little salt. It differs from heat cramps in that systemic symptoms occur. Symptoms are similar to those seen in water depletion heat exhaustion; the body temperature usually remains nearly normal.
Clinical Features

The symptoms and signs associated with both types of heat exhaustion are variable and include weakness, fatigue, frontal headache, impaired judgment, vertigo, nausea and vomiting and, occasionally, muscle cramps (Box 133.3). Orthostatic dizziness and syncope can occur. Sweating persists and may be profuse. The core temperature is only moderately elevated, usually below 40°C (104°F), and signs of severe CNS dysfunction (eg, altered mental status) are not present.

Differential Diagnosis

Mild heat exhaustion and full-blown heatstroke represent extremes of the spectrum of heat illness, and intermediate cases may prove difficult to differentiate. Nevertheless, heat exhaustion should not be diagnosed in the presence of major CNS dysfunction (eg, seizures, coma) or severe hyperthermia (40.5°C [104.9°F]).

Diagnostic Testing

This syndrome is characterized by hyponatremia, hypochloremia, and low urinary sodium and chloride concentrations. The creatine phosphokinase (CPK) level and renal function should be determined. Measurement of hepatic transaminase levels may prove helpful. Elevations to several thousand units can be seen in patients with heat exhaustion or in healthy runners after a marathon, whereas in patients with heatstroke, such levels are usually in the tens of thousands after 24 hours.

Management

Pure forms of either type of heat exhaustion are rare, and most cases of heat exhaustion involve mixed salt and water depletion. Heat exhaustion is primarily a volume depletion problem, and rapid recovery generally follows fluid administration. Decisions regarding the type of fluid and electrolyte replacements should be based on serum electrolyte level measurements and the estimation of hydration status by clinical and laboratory parameters.

Patients with significant volume depletion or electrolyte abnormalities require IV fluids. If the patient is orthostatic, normal saline should be administered until vital signs normalize. Free water deficits should be replaced slowly during 48 hours to avoid a decrease of serum osmolality of more than 2 mOsm/hr. Overly rapid correction of hypernatremia is associated with cerebral edema and seizures.

Disposition

Young, otherwise healthy patients who do not have significant laboratory abnormalities and who respond rapidly to hydration do not require hospitalization. These patients should be instructed to drink plenty of fluids and avoid heat stress for 24 to 48 hours.

Older patients, particularly those with cardiovascular disease or other chronic diseases, may benefit from more cautious inpatient fluid and electrolyte replacement and frequent reassessment (Box 133.4).

Heatstroke

Principles

In the previously discussed forms of heat illness, although the body temperature rises, homeostatic thermoregulatory mechanisms remain intact. Heatstroke is the catastrophic life-threatening emergency that occurs when these mechanisms fail. This failure results in the elevation of body temperature to extreme levels, usually higher than 40.5°C (105°F), producing multisystem tissue damage and organ dysfunction.

As heatstroke develops, energy will be insufficient to sustain thermoregulatory mechanisms, resulting in dramatic increases in core temperature and the clinical manifestations of heatstroke. Tissue damage is a function of a complex interaction of body temperature, exposure time, workload, tissue perfusion, and individual factors. The exact temperature at which cellular damage begins to occur in an individual patient varies. Full recovery is possible, despite rectal temperatures up to 46.5°C (115.7°F).

Neurologic dysfunction is a hallmark of heatstroke, and cerebral edema is common. Other pathologic changes include petechiae in the walls of the third and fourth ventricles and marked cerebellar Purkinje cell damage.14 Interestingly, the hypothalamus, the predominant site of central thermoregulatory control, is usually not damaged.

Heat stress creates tremendous demands on the cardiovascular system, and patients who succumb to heatstroke show signs of circulatory failure. Although such pathologic changes are common, cardiac damage alone is not lethal.

Prolonged heat stress produces impressive increases in skin blood flow (peripheral vasodilation) and a reduction of the thermal gradient between the core and the skin (Fig. 133.4). Functional hypovolemia is avoided by compensatory vasoconstriction of the splanchnic and renal vasculatures. The resulting splanchnic and renal ischemia may explain the nausea, vomiting, and diarrhea observed in runners after a marathon. Hepatic damage is a consistent feature of heatstroke, and its absence should cast doubt on the diagnosis.

If severe heat stress continues, compensatory splanchnic vasoconstriction will eventually fail, resulting in reduced mean arterial pressure and a continued cascade of exaggerated systemic inflammatory responses. Failure to perfuse the skin with heated blood from the core results in a dramatically increased rate of heat storage. This produces elevated intracranial pressure, which, in
**Clinical Features**

**Heatstroke Versus Heat Exhaustion.** The onset of heatstroke is sudden, and the patient’s level of consciousness is altered. Prodromal symptoms lasting minutes to hours occur in approximately 20% of cases. These are nonspecific and may include weakness, dizziness, nausea, vomiting, anorexia, frontal headache, confusion, drowsiness, disorientation, muscle twitching, ataxia and signs of cerebellar dysfunction, and psychiatric symptoms, ranging from anxiety and irritability to psychosis. These prodromal symptoms are reminiscent of the description of heat exhaustion. Heat exhaustion, particularly the water depletion variety, can progress to heatstroke if untreated.

The usual manifestations of heatstroke include hyperpyrexia above 40.5°C (105°F), profound CNS dysfunction, and hot skin (Box 133.5). Persistent sweating can be observed in patients with rectal temperatures of 41.5°C to 42.4°C (106.7°F–108.3°F). In one large series of exertional heatstroke victims, sweating persisted in 50% of cases. Therefore, the cessation of sweating is not the cause of heatstroke, and continued sweating does not preclude the diagnosis.

Although in heatstroke the core temperature is elevated above 40.5°C (105°F), significant cooling may occur in the out-of-hospital phase, and the first temperature obtained in the emergency department (ED) may not represent the original maximum core temperature.

**BOX 133.5**

**Heatstroke: Diagnosis**

- Exposure to heat stress, endogenous or exogenous
- Signs of severe central nervous system dysfunction (coma, seizures, delirium)
- Core temperature usually > 40.5°C (105°F), but may be lower
- Hot skin common, and sweating may persist
- Marked elevation of hepatic transaminase levels

**Classic Heatstroke Versus Exertional Heatstroke.** The two forms of heatstroke have significantly different presentations and manifestations—classic (epidemic) heatstroke (CHS) and exertional heatstroke (EHS; Table 133.1).

CHS occurs during periods of sustained high ambient temperatures and humidity, such as during summer heat waves. Victims are often older adults and poor and live in underventilated dwellings without air conditioning. Debilitated patients who have limited access to oral fluids may develop water depletion heat exhaustion, which progresses to heatstroke if untreated. Victims of CHS commonly suffer from chronic diseases, alcoholism, or schizophrenia, which predisposes to heat illness. Such patients are often prescribed medications (eg, diuretics, antihypertensives, neuroleptics, anticholinergics) that impair the ability to tolerate heat stress. Sweating ceases in most CHS patients. Factors such as advanced age, hypotension, altered coagulation status, and the necessity for endotracheal intubation on arrival at the ED predict a poor outcome, despite successful cooling measures.

In contrast, patients with EHS are usually young and healthy individuals whose heat-dispelling mechanisms are overwhelmed by endogenous heat production. Athletes and military recruits are typical victims. Rhabdomyolysis and acute renal failure, rarely seen in patients with CHS, are common in patients with EHS. Sweating is present in 50% of cases of EHS. Hypoglycemia may occur as the result of increased glucose metabolism and hepatic damage, resulting in impaired gluconeogenesis. Coagulopathy is common; the mechanism is depicted in Fig. 133.5.

Hyponatremia with serum sodium levels of less than 130 mmol/L has been detected in summer hikers in the Grand Canyon; many were found to have with neurologic symptoms or seizures. Signs of profound CNS dysfunction dominate the early course of heatstroke. Delirium or coma is characteristic, but virtually any neurologic abnormality, including bizarre behavior, opisthotonus, hallucinations, decerebrate rigidity, oculogyric crisis, and cerebellar dysfunction, can be seen. Convulsions occur in up to 75% of patients and can be precipitated by therapeutic cooling maneuvers. Profound muscle rigidity with tonic contractions, coarse tremor, and dystonic movements can mimic seizures. Pupils may be fixed and dilated, and the electroencephalogram may be isoelectric. All these changes are potentially reversible, although permanent damage, including cerebellar deficits, hemiplegia, dementia, and personality changes, is common in severe...
cases. Patients with heatstroke usually have hyperdynamic cardiovascular systems with low peripheral vascular resistance, tachycardia (up to 180 beats/min), and an elevated cardiac index. Elevation of cardiac troponin I is not uncommon with CHS; however, it is rarer in EHS. The central venous pressure (CVP) is usually elevated. The combination of elevated CVP with right-sided cardiac dilation suggests right-sided heart failure, which is also seen after shock or sepsis. These changes are expected because skin blood vessels dilate to dissipate heat; however, this low peripheral vascular resistance has persisted in patients after reduction of body temperature to nearly normal.

Respiratory alkalosis is a physiologic response to active or passive heating and may be severe enough to produce tetany. Although most patients with CHS have respiratory alkalosis, those with EHS usually have a relatively pure lactic acidosis. Lactic acidosis is associated with a poor prognosis in cases of CHS but not necessarily in cases of EHS. Both CHS and EHS cause the hemoglobin-oxygen dissociation curve to shift to the right. An increase in the temperature denatures the bond between oxygen and hemoglobin, decreasing the concentration of oxyhemoglobin. Aberrations in coagulation are common in patients with severe heatstroke, and their presence is a poor prognostic sign. Abnormal hemostasis is manifested clinically by purpura, conjunctival hemorrhage, melena, bloody diarrhea, hemoptysis, hematuria, myocardial bleeding, or hemorrhage into the CNS. Diarrhea, probably caused by intense splanchnic vasoconstriction, is commonly seen. Cooling aggravates the diarrhea, creating an unpleasant treatment problem. Pancreatitis is described, with elevated serum amylase and lipase levels.

**Differential Diagnosis**

Heatstroke occurs when the thermoregulatory responses are overwhelmed and fail. If the patient is evaluated as this is occurring, differentiation between heat exhaustion and heatstroke is difficult. If heatstroke cannot be excluded, efforts to cool the patient should begin immediately. Only after the initial assessment and cooling have been initiated is the differential diagnosis relevant. When a history of collapse under conditions of heat stress is present, rapid improvement in mental status and blood pressure with cooling essentially eliminates alternative diagnoses. If, however, the temperature does not respond, and the patient does not recover neurologically, other causes of fever and coma should be considered (Box 133.6).

**Meningitis and Encephalitis.** These can masquerade as heatstroke. In patients with heatstroke, the spinal fluid should be clear, with occasional lymphocytic pleocytosis and elevated protein levels. Cerebral falciparum malaria, which has a classical picture of high fever and encephalitis, is seen in tropical areas where heat illness can also occur.

**Thyroid Storm.** In patients with thyroid storm, the clinical symptoms resemble those of heatstroke. It should be suspected if the thyroid gland is enlarged or nodular, but a normal thyroid gland does not exclude the diagnosis. Thyroid function test results are elevated, but these are not available on an emergency basis. Fortunately, thyroid storm is rare, and some critical aspects of treatment, such as rapid cooling, coincide with those for heatstroke.

**Drug-Induced Heat Illness.** This is an important consideration, particularly anticholinergic poisoning. Differentiation may be difficult because heatstroke and anticholinergic poisoning cause hyperpyrexia, hot and dry skin, tachycardia, and abnormal mental status. Constricted pupils are present in many heatstroke patients. Mydriasis should be present in patients with anticholinergic poisoning, and its absence argues strongly against this diagnosis. Typhoid fever, typhus, delirium tremens, and hypothermic hemorrhage all produce a symptom complex similar to that of heatstroke.

Drug overdose of sympathomimetics or stimulants, such as amphetamines, cocaine, and phenylcaine, can cause fatal hyperpyrexia. A high ambient temperature is associated with a significant increase in mortality from cocaine overdose. Many younger patients who die of hyperthermia test positive for cocaine. Heatstroke can occur with delirium resulting from ethanol withdrawal. Aspirin and clopidogrel attenuates the skin vasodilatory response and shifts the onset of peripheral thermoeffector mechanisms toward a higher body temperature during exercise heat stress. Heatstroke has occurred in well-trained military soldiers and athletes who ingested dietary supplements containing ephedrine or the ergogenic aid creatine. Some antipsychotics also cause suppression of thirst recognition. Individuals with a history of heatstroke, with or without an inherent aberration that predisposed them to the initial episode, are at increased risk for a recurrence.

**Neuroleptic Malignant Syndrome.** This is induced by antipsychotic medications and is characterized by muscle rigidity, severe dyskinesia or akinesia, hyperthermia, tachycardia, dyspnea, dysphagia, and urinary incontinence. Although the so-called lead

pipe rigidity and hyperthermia are reminiscent of malignant hyperthermia, the putative mechanism is different. Dopamine receptor blockade in the corpus striatum caused by butyrophenones (eg, haloperidol) and similar agents produces severe muscle spasticity and dystonia, leading to the overproduction of heat (see Chapter 155).

Serotonin Syndrome. This can also mimic heatstroke because of the elevated body temperature tremors, clonus, and CNS alterations that occur. Serotonin syndrome is classically a triad of mental status changes, autonomic hyperactivity, and neuromuscular abnormalities secondary to increased CNS serotonergic activity. A history of recent exposure to an illicit or therapeutic medication is an important clue (see Chapter 146).

Diagnostic Testing

Most standard measurements of body temperature vary significantly from the actual core temperature. Oral thermometry is affected by mouth breathing and is a poor approximation of the core. Rectal thermometry is less variable but responds to changes in core temperature slowly. Thermistors that are inserted 15 cm into the rectum offer continuous monitoring of temperature and have less variability. Although rectal measurements are slower to respond to changes in core temperature than tympanic temperature readings, rectal measurements are not biased by head skin temperature. An esophageal thermistor positioned adjacent to the heart is another option.

The hematologic evaluation should include arterial blood gas determination, complete blood cell and platelet counts, electrolyte values (including calcium), and glucose, blood urea nitrogen, and serum creatinine levels. Hypoglycemia with a serum glucose level less than 65 mg/dL is often found in cases of EHS. With the risk of acute rhabdomyolysis, the creatine kinase and myoglobin levels should be measured and urinalysis performed. Severe heatstroke can induce disseminated intravascular coagulation (DIC); therefore, prothrombin and partial thromboplastin times, international normalized ratio, and fibrin degradation products should be measured. Serum cardiac troponin I levels should be obtained. Metabolic acidosis is common, especially in patients with EHS. Lactate levels are usually elevated and may persist or even worsen with improved extremity perfusion.

Renal damage is common. The initial urine specimen, usually obtained by catheterization, is a scanty, brownish, turbid fluid resembling machine oil. Microscopic examination reveals proteinuria, with abundant granular casts and red blood cells. Acute oliguric renal failure complicates 25% to 30% of EHS cases and 5% of CHS cases. The glomerular filtration rate, renal plasma flow, urine flow, and sodium excretion diminish markedly during exercise. Heavy physical exertion in hot climates produces acidic and maximally concentrated urine, which can result in acute oliguric renal failure in combination with hypotension and myoglobinuria.

Because heatstroke patients are prone to liver failure, aspartate transaminase, alanine transaminase, lactate dehydrogenase, and liver other enzyme levels should be monitored. Hepatic transaminase level elevations may be diagnostically helpful. In most febrile states that include altered mental status or coma, these enzyme levels will be normal or minimally elevated, although they are usually dramatically elevated early in the course of heatstroke. Hepatic damage is consistently featured in heatstroke. Hepatic injury is evidenced by markedly elevated levels of hepatic amino-transferases (serum aspartate transaminase and alanine transaminase). Early experimental models have shown that high-mobility group box 1 (HMG1) as a mediator of systemic inflammation is elevated in heatstroke, and its inhibition may be liver-protective. Jaundice typically appears 24 to 72 hours after the onset of severe heatstroke and gradually recedes if the victim survives. Survivors generally have no permanent impairment of liver function.

Management

Cooling. Immediate cooling is the cornerstone of treatment. Patients who present to the hospital with heatstroke have high mortality rates ranging from 21% to 63%, and mortality increases significantly when cooling is delayed. A thermistor probe should be inserted as soon as possible, and the patient’s temperature should be continuously monitored.

Evaporative cooling is recommended because it is effective, easy to perform, noninvasive, and less likely to interfere with other patient care activities than other cooling techniques. The patient is stripped of all clothing, and tepid tap water is sprayed while fans blow air continuously over the body, causing evaporative cooling. One reported method of evaporative cooling uses a body cooling unit on which the patient lies suspended on a net surface while being sprayed with atomized 15°C (59°F) water from above and below. Air warmed to 45°C to 48°C (113°F–118.4°F) is blown over the skin surface at a rate of 3 m/min. This approach maximizes evaporative cooling by maintaining cutaneous vasodilation and avoiding heat generation caused by shivering. When the patient’s body temperature reaches 39°C (102.2°F), cooling measures should be discontinued to avoid hypothermic overshoot. Continuous monitoring is necessary to maintain the core temperature at 37°C to 38°C (98.6°F–100.4°F).

Immersion in ice water results in a rapid reduction of core temperature to below 39°C within 10 to 40 minutes but can complicate the resuscitation process. Vigorous skin massage to maintain cutaneous circulation has been advocated, but there is no evidence that this is efficacious. Military studies of EHS patients treated with ice water immersion have reported no fatalities or permanent sequelae. Immersion is technically difficult in the ED. Vasoconstriction from ice water immersion may be beneficial to hypotensive patients and may be better than evaporative cooling for victims in shock who have poor peripheral circulation.

Cooling modalities other than evaporation and immersion should be considered adjunctive treatments (Box 133.7). Application of ice packs to high heat transfer areas (eg, neck, groin, axillae) is commonly used. Cooling blankets may be a useful adjunct but will not produce rapid cooling if used exclusively. Cold irrigant gastric or rectal lavage will not provide significant heat exchange if used as the primary cooling modality. Antipyretics have no role in the treatment of heat-related illness.

Resuscitation. Mortality correlates with the temperature and number of dysfunctional organ systems, with an increased risk of death if patients present with anuria, coma, or cardiovascular failure. Aspiration and seizures are common in patients with heatstroke, and airway control is indicated. Hypoxemia may occur because of aspiration, pneumonitis and pulmonary infarction, hemorrhage, or edema. Metabolic demands are high, and normal pulmonary ventilation may be inadequate in this setting.

Crystalloid fluid resuscitation is essential. Circulatory fluid requirements are modest in some cases, averaging 1200 mL of isotonic crystalloid solution in the first 4 hours. Pulmonary edema occurs in patients with heatstroke and can be exacerbated by overzealous fluid administration. The use of a CVP catheter to monitor fluid resuscitation may be deceptive. Most patients may require only modest IV fluids because cooling produces vasoconstriction and increases blood pressure. Hypotension is common in patients with heatstroke and is usually caused by peripheral vasodilation resulting in high-output cardiac failure in addition to dehydration. Blood pressure usually rises with cooling. If this does not occur, or if the patient being monitored invasively has a low CVP, a fluid challenge of 250 to 500 mL of 0.9% saline should be given rapidly while blood pressure, pulse, and urine output are monitored. Fluid replacement is continued until the blood pressure reaches 90/60 mm Hg or the CVP exceeds 12 mL H₂O. On occasion, patients exhibit hypodynamic responses with a low cardiac index, elevated CVP, and hypotension. These patients may be cyanotic, whereas patients with hyperdynamic circulation are initially pink. This clinical observation can be helpful in identifying patients who may respond to catecholamines.

A variety of tachyarrhythmias commonly occur during heatstroke. These usually resolve with cooling, and electrical cardioversion should be avoided as the myocardium is adequately cooled. The use of α-adrenergic agents such as norepinephrine is not recommended because they promote vasoconstriction without improving cardiac output or perfusion, decrease cutaneous heat exchange, and may exacerbate ischemic renal and hepatic damage. Atropine and other anticholinergic drugs that inhibit sweating should be avoided. Neuroleptics, like chlorpromazine, should be avoided. These agents have anticholinergic properties that can interfere with sweating and cause hypotension or precipitate seizures. Many patients are extremely agitated during the initial cooling period. Short-acting benzodiazepines can be used for sedation and to control seizures. Barbiturates are less desirable because the metabolism is altered by hepatic dysfunction.

Coagulopathies can occur during the first day of illness but are more common on the second and third days. Initial treatment after cooling should include replacement therapy with fresh-frozen plasma and platelets. The emergency clinician should monitor the laboratory signs of DIC—(hypofibrinogenemia, elevated fibrin split products, prolonged prothrombin time, and thrombocytopenia. The bleeding diathesis seen in patients with heatstroke may be the result of fibrinolysis. Although α-aminoacaproic acid can impede fibrinolysis, administration of this compound is associated with rhabdomyolysis, and its use is not recommended in patients with heatstroke.

Disposition

Patients presenting with classic or exertional heat stroke should be stabilized in the ED, with admission to an intensive care setting. Patients with more complex end-organ damage (eg, renal failure requiring dialysis) may require transfer to a center with more comprehensive tertiary care capabilities.

**KEY CONCEPTS**

- Classic heatstroke is generally diagnosed in older patients with comorbidities during heat waves, whereas exertional heatstroke is more common in young athletic patients or military personnel.
- Patients with exertional heatstroke are commonly diaphoretic.
- Rapid cooling of the potential heatstroke patient should be initiated before the diagnosis is firmly established. The most effective minimally invasive cooling measure is with evaporative techniques using cool mist sprays and standing fans.
- Antipyretics are ineffective and should not be used to control environmental hyperthermia.
- Heatstroke can cause right-sided cardiac dilation and elevated CVP and clinically resemble pulmonary edema, but still requires vigorous crystalloid resuscitation.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
The onset of heatstroke is sudden. Prodromal symptoms lasting minutes to hours can occur that are nonspecific and similar to those of heat exhaustion. Signs and symptoms may include weakness, dizziness, nausea, frontal headaches, confusion, muscle twitching, ataxia and signs of cerebellar dysfunction, and psychiatric symptoms, ranging from anxiety and irritability to psychosis. Heat exhaustion can progress to heatstroke if it is untreated. If the patient is evaluated as this is occurring, differentiation between heat exhaustion and heatstroke is difficult. If heatstroke cannot be excluded, efforts to cool the patient should begin immediately.

Whereas rest is part of the treatment for heat exhaustion, it is not the only treatment. She must be removed from the hot environment, not be allowed to finish the race, and assessed for her volume status. Normal saline is used to replete volume if the patient is orthostatic; free water deficits are replaced slowly to avoid cerebral edema.

Which of the following regarding heat exhaustion is true?

A. It causes body temperatures that often exceed 40.5°C (105°F).
B. It exists in two discrete forms, salt depletion and water depletion.
C. It is associated with systemic symptoms.

D. It is characterized by hyponatremia and hyperchloremia.
E. It occurs when muscles are fatigued by heavy work.

Answer: C. Heat exhaustion is a clinical syndrome. Whereas there are typically two types of heat exhaustion, water depletion and salt depletion, pure forms of either type are rare. Most cases of heat exhaustion involve mixed salt and water depletion. In salt depletion, pure forms of either type are rare. Most cases of heatstroke patients with which of the following?

A. Altered coagulation status
B. History of schizophrenia
C. Need for 100% oxygen
D. Presentation with acute renal failure
E. Presentation with acute rhabdomyolysis

Answer: A. Factors such as advanced age, hypotension, altered coagulation status, and the necessity for endotracheal intubation on arrival at the ED predict a poor outcome, despite successful cooling measures.

The usual characteristics of classic heatstroke include which of the following?

A. Diaphoresis
B. Disseminated intravascular coagulation
C. Hypoglycemia
D. Marked lactic acidosis
E. Usual occurrence during heat waves

Answer: E. Usual characteristics of classic heatstroke include predisposing factors or medication, older population, sedentary lifestyle, anhidrosis, normoglycemia, mild coagulopathy, mild elevation in creatine kinase level, oliguria, mild acidosis, and occurrence during heat waves. Diaphoresis, hypoglycemia, disseminated intravascular coagulation, and marked lactic acidosis are characteristics of exertional heatstroke.

CHAPTER 134

Lightning and Electrical Injuries

Kelly P. O’Keefe | Rachel Semmons

PRINCIPLES

Background

Electrical Injury

The first recorded death from electric shock occurred in 1879 in Lyons, France, after a carpenter sustained an injury from a 250-V alternating current source. The first electrocution in the United States occurred in 1901, when an intoxicated gentleman made contact with a DC generator terminal in front of a World’s Fair crowd in Buffalo, New York. The patient’s death appeared to be quick and painless, prompting the suggested use of electrocution for capital punishment.

Electrical injuries have a trimodal age distribution. Toddlers and younger children experience low-voltage injuries in the household as the result of contact with electric sockets and cords. Adolescents and young adults more frequently experience high-voltage injury from contact with electric lines outside of houses. Another peak occurs in the third to fourth decade of life, almost exclusively in men with occupational injuries due to high-voltage encounters with power lines and, to a lesser extent, from electric tools. Electrical injuries comprise only a small percentage of workers’ compensation claims but are the second highest source of indemnity and paid medical claims, responsible for many days of lost work, and are significant causes of permanent disability. Electrical burns comprise only a small percentage of admissions to burn centers, but these patients have a more prolonged hospital course, require more interventions (eg, fasciotomies, escharotomies, amputations), and have higher mortality rates than patients with thermal burns.

Although electrical injuries from inadvertent household and occupational exposure have been on the decline, the use of electronic conduction weapons (eg, Tasers, stun guns) is increasing. These weapons, which deliver brief bursts of high-voltage, low-amperage direct current, are favored by law enforcement because they incapacitate subjects with minimal morbidity and lethality. Industry manufacturers report over 1.5 million discharges since the unwind of repairman.

Lightning

The incidence of lightning-related deaths in the United States has declined from a long-standing average of over 100/year to less than 40/year in recent times, perhaps as the result of American urbanization. Approximately 10% of lightning strike victims die, usually within the first hour from fatal arrhythmias or respiratory failure, and most survivors suffer permanent disabilities. Victims are most commonly young males who work or play outdoors in the spring and summer months, often during thunderstorms. Lightning usually strikes single victims but injuries to multiple victims can occur when a bolt lands in an outdoor group, often athletes or observers at sporting activities.

Physics of Electricity

Electrical Injury

The degree of injury from electrical shock depends on multiple factors, including the type of circuit, current, resistance (measured in amperes), voltage, duration of contact, and pathway of flow (Box 134.1).

Type of Circuit. Electrical sources create current that flows in one direction (direct current, DC) or alternates direction cyclically at varying frequencies (alternating current, AC). The few systems that use DC include batteries, automobile electronics, and railroad tracks. Exposure to DC most frequently causes a single, strong, muscular contraction. This may throw the subject back from the source in a way that limits duration of exposure but can result in other injuries. AC is more commonly used (eg, household currents) because it conveniently allows for an increase or decrease of power at transformers. It is more dangerous than DC of similar voltage because amperage above the so-called let-go current will cause muscular tetanic contractions. Because the flexor muscles of the upper extremities are stronger than extensor muscles, these contractions pull the victim closer to the source and result in prolonged exposure. Box 134.2 shows the physical effects of different amperage levels at a common 60-Hz AC exposure. Capacitors store electric charge in circuits, and discharge from these devices may result in sudden bursts of very large amounts of electrical energy. Injury from a capacitor may occur even when the electrical device is not energized (plugged in), often involving the unwary repairman.

Current. Current is the flow of electrons down an electrical gradient. It is measured in units of amperage. According to Ohm’s law, current is directly proportional to the voltage of the source and inversely proportional to the resistance of the material through which it flows. Key laws regarding the physics of electrical injury are summarized in Box 134.3.

Resistance. Resistance is the degree to which a substance resists the flow of current; it varies among body tissues. Neurovascular tissues are good conductors of electricity, whereas tendons, fat, and bone are relatively poor conductors (Box 134.4). Within a given tissue, resistance differs based on the fluid and electrolyte content of cells. Dry skin offers the largest resistance, up to 100,000 ohm (\(\Omega\)) in thick, calloused skin, but dermal resistance decreases to as little as 1000 \(\Omega\) when wet. Current that is initially unable to pass through skin will create thermal energy and cause significant burns. As the skin blisters and deteriorates, its resistance decreases.

Current may jump across skin surfaces in a behavior called arcing, resulting in prominent burns across flexor surfaces. Internally, current follows the path of least resistance, and the degree of burns seen on the surface typically underestimates the damage occurring below the surface. As current strength increases, the...

Voltage is not the only factor responsible for damage, but it is often the only property that is known in cases of electrical injury. As a result, injuries are conventionally classified as being caused by high- or low-voltage sources, with 1000 V as the dividing line. In the United States and Canada, household sources are low voltage, typically 120 or 240 V. High-voltage injuries are impressively characterized by partial- to full-thickness skin burns, deep tissue destruction, and frequent cardiac or respiratory arrest. Low-voltage exposure causes less surface damage, but may be equally lethal, particularly in cases in which skin resistance is low.

**Duration of Contact.** The degree of tissue damage is directly proportional to the duration of exposure for all voltage levels. Exposure times greater than the length of one cardiac cycle tend to generate arrhythmias, likely in a manner analogous to the R-on-T phenomenon.

**Pathway.** The pathway followed by electrical current determines morbidity and mortality. The entrance and exit sites of the electrical current typically demonstrate greater evidence of skin damage, with full-thickness burns commonly encountered. These sites are properly referred to as the source and ground contact points. A patient may have one or multiple source and ground contact points. The most common locations are the hands, wrists, and arms, but children also present with burns from oral contact with electric cords or sockets. The most common ground contact points are the heels.

Electrical current passing through a limb causes greater local tissue damage than current passing through the trunk because the smaller cross-sectional area limits the ability to dissipate heat. However, current passing through the trunk results in greater mortality due to the involvement of more vital organs. Transthoracic pathways (arm to arm) are more likely to generate arrhythmias and have higher mortality rates than vertical currents (leg to arm) or straddle pathways (leg to leg).³

**Conducted Electrical Weapons.** The most commonly used conducted electrical weapon (CEW) is the Taser X26 (Fig. 134.1). The weapon consists of a hand-held unit with two barbs deployed through connecting cables. The sharp portions of these barbs are 9 mm thick (Fig. 134.2) and typically lodge in the skin, but can discharge current through clothing as well. The standard initial discharge is a 5-second burst of stimuli at 19 Hz. The peak voltage delivered to the subject is 1200 V, but the amperage is low, at 2.1 mA. The primary burst is followed by 100-msec pulses.
intended to inhibit myoneurons, causing the subject to fall to ground. These weapons can also be used as a direct contact device in a technique called drive stun. When used in this way, the unit’s barbs are not deployed, and the subject experiences pain, but not muscular paralysis. Newer commercial devices designed for personal protection have the potential for increased amperage and time of exposure, thereby increasing the opportunity for more detrimental outcomes.\(^7\)

**Lightning Injury**

Although the same basic scientific principles of electricity apply to lightning, there are several major differences. Lightning strikes involve hundreds of millions of volts, significantly more than those from electrical sources. In contrast, the duration of contact is drastically shorter, averaging 30 microseconds. As a result, current flow is altered, with a reduction in penetration causing less destructive tissue effects overall.

Lightning occurs as the result of a tremendous potential difference between positively and negatively charged particles. Water particles carried on warm updrafts rise from the earth and are cooled in the upper air, where cloud formation takes place. The phase change of the water from gas to liquid, and even solid, is associated with the generation of an electric charge. An intense electric field is created, with positive charges concentrated in the upper portions of the cloud and negative charges in the lower portions. The earth, which is normally negatively charged with respect to the atmosphere, becomes positively charged when the thunderstorm, with its negatively charged cloud base, passes overhead. A potential difference in charge as great as 100 to 300 million volts is created in this process. When the potential difference surpasses the resistance of the intervening air and other elements, a lightning bolt, like a huge spark, is generated. Initially, small sparks are emitted and travel a short distance from the ground upward, but these enlarge quickly as the distance between charged items shortens and the potential difference increases. Pilot strokes from the ground eventually meet a leader stroke from the cloud, a conducting pathway is created, and a massive surge of electrical discharge follows. It takes approximately 20 milliseconds for a leader to reach the ground from the cloud, but only 20 microseconds for the return stroke from the ground up to be completed. Several discharges may take place in the same channel, with each discharge often exceeding 10 million volts. Thunder is a result of the superheating of the channel (estimated at 50,000°F [27,760°C]), which causes rapid expansion and compression of the local air, creating a tremendous sound pulse. Lightning takes various forms, described as streaked, forked, ribbon, sheet, or beaded. The most unusual form is ball lightning, which appears as a globe, rolls along structures, and may even pass through open doors or windows. Strikes occur from cloud to cloud, cloud to ground, or even ground to cloud.

Lightning may strike a person directly, strike a tree or other object and injure anyone in direct contact with it (contact voltage), or strike its target and then travel through the air to affect the victim (side flash, or splash injury). A person’s chances of being struck are increased by wearing or carrying metal objects or other conductors. Side flashes may travel as far as 30 m after striking the first object to affect another. Lightning may also strike the ground and be conducted to the victim. A greater distance from the ground strike lessens transmission of the charge. The risk of injury from a ground strike is increased when one contact point on the victim (eg, the right foot) is closer to the strike than a second contact point (eg, the left foot), thus creating a potential difference. This is referred to as stride voltage and is likely responsible for cattle deaths in a pasture after a thunderstorm. Hence, when out in the open during a storm, caution must be taken to place an insulating material, such as a raincoat, between the ground and the body and assume the lightning position—a squatting configuration with the feet together—or to curl up in a ball on the ground to reduce the number of contact points. Box 134.5 lists tips for avoiding lightning strikes.

Lightning Injury occurs from the force of a strike, blunt trauma effects when the victim is thrown, the superheating of metallic objects in contact with the patient, blast-type effects and barotrauma, or shrapnel.

**CLINICAL FEATURES**

**Electrical Injury**

**General Tissue Effects**

At the cellular level, current causes damage to cell membranes and alters membrane solubility, leading to electrolyte abnormalities and cellular edema. This process, termed *electroporation*, eventually leads to irreversible cell damage and death.\(^7\) At the tissue and organ levels, electrical current produces damage when electrical energy is converted to thermal energy.

**Skin**

Most electrical injuries result in skin burns, which fall into one or more of four patterns (Box 134.6). The relatively high resistance...
Dysrhythmias are seen immediately or in a delayed fashion following electrical injury. These include malignant arrhythmias, but more frequently involve sinus tachycardia or bradycardia, atrial fibrillation, and ectopic beats. A variety of electrocardiographic abnormalities may be present, including transient ST elevation or depression that does not correlate with myocardial ischemia or infarction. Injury to coronary arteries or directly to the myocardium may result in infarction, but this is rare. Nonspecific cardiac biomarker levels are frequently elevated in the period following electrical injury, but this is usually due to skeletal muscle injury and is only rarely related to cardiac damage.

**Head and Neck**

Ocular involvement is common following exposure to electrical current, with cataracts being the most frequent manifestation. Other forms of injury include vitreous and anterior chamber hemorrhages, retinal detachment, macular lacerations, and corneal or conjunctival burns. Injury to structures of the eye is less common, but sensorineural deafness can be seen as a result of nerve damage. Patients frequently develop vertigo, which may be transient or persistent. Toddlers and young children sustain orofacial injuries after chewing or sucking on electrical cords or from lingual contact with sockets. Full-thickness burns may be sustained on the mucous membranes and lips, with destruction to the tongue and teeth as well. Injuries to the oral commissure produce cosmetic difficulties and, more significantly, the well-recognized complication of delayed labial artery bleeding, typically occurring 2 days after injury, when the resultant eschar separates from the wound.

**Extremities**

Neurovascular bundles have low resistance and are particularly prone to damage from electrical current. Muscle necrosis occurs primarily or is secondary to compromise of the blood supply. Vascular injury is most prominent at the intimal and medial layers. Involvement of the intima results in immediate coagulative necrosis and thrombosis, whereas injury to the media causes aneurysmal dilation and hemorrhage in a delayed fashion. Decreases in tissue perfusion lead to edema and tissue death. Areas of infarction may be distributed sporadically throughout the injured region, with areas of surviving tissue adjacent to necrotic tissue. Muscle that initially appears viable may deteriorate with time, especially in the periosteal regions. Endothelial and smooth muscle function are depressed for many weeks following the initial injury, contributing to a hypercoagulable state that increases the risk of delayed deep venous thrombosis. The combination of tissue edema and perfusion defects makes compartment syndrome likely, with fasciectomy and even amputations required. Cyanosis or pulselessness may be transient or may indicate permanent damage; in a similar fashion, limbs that appear initially well perfused may later necrose.

Bony injury is common. Because bone is highly resistant to electrical current flow, great amounts of heat are generated, resulting in periosteal burns and osteonecrosis. Exposure to DC typically causes a single, strong muscle contraction, throwing the victim away from the electrical source. This can result in a variety of skeletal injuries, including fractures or dislocations. Exposure to AC causes muscular tetany, which occasionally results in similar skeletal injuries.

**Nervous System**

Electrical injury damages the central and peripheral nervous systems. The most common immediate central symptoms are altered mentation, seizure, and/or coma. Seizures may occur as an isolated event or as a lasting seizure disorder. Vascular injury may cause cerebral infarction, and secondary trauma may result in intracranial hemorrhage. Cerebral venous sinus thrombosis has been reported.

Patients may experience transient spastic paralysis with accompanying sensory deficits immediately following electrical injury.
Delayed and chronic manifestations include ascending paralysis, transverse myelitis, and amyotrophic lateral sclerosis. Peripheral neuropathies are a common result, most often involving the median and ulnar nerves.

Neuropsychiatric sequelae include anxiety, depression, mood lability, difficulty concentrating, and insomnia. These may become a persistent source of disability.8

Other Viscera

Extensive muscle damage may result in significant myoglobinuria, subsequent renal failure, and life-threatening hyperkalemia. These complications are more likely in patients who are hypotensive or volume-depleted.

Stress ulcers are a common gastrointestinal complication. Uncommon but severe intra-abdominal injuries include a ruptured hollow viscus and necrosis of the pancreas or gallbladder. Pulmonary edema is rare. Although early deaths are due to respiratory and cardiac arrest, late deaths occur from sepsis, pneumonia, and renal failure. For obstetric patients, the overall risk to the fetus is small, but a spontaneous abortion can occur. Secondary trauma may lead to placental abruption.

Clinical Features After Discharge of a Conducted Electrical Weapon

Most patients who sustain shock from a CEW do not need medical treatment. Barbs usually attach to the chest or back, although there is potential for penetration of more sensitive areas, such as the genitals, face, eyes, or skull. Patients frequently have minor transient increases in heart rate and variable effects on blood pressure. Transient, clinically insignificant electrocardiographic changes include sinus arrhythmia, PR shortening, and ST changes. More concerning findings, such as alterations in QRS or QT intervals, have not been reported. At least one study has demonstrated no significant increases in troponin after discharge. Secondary injuries rarely result from the victim falling to the ground while incapacitated. Use of these devices has been cited as a potential factor in police custody deaths of patients with multiple comorbidities including psychiatric conditions, intoxication, and excided delirium, although the mechanism is unknown and the causation unclear.2

Lightning Injury

Cardiovascular System

The most severe effects of lightning strike are cardiac and respiratory arrest. The massive surge causes cardiac standstill and cessation of all respiratory efforts. Therefore, the initial arrhythmia is asystole. At some point, the intrinsic pacemaker activity of the heart brings about a resumption of cardiac activity. However, if the respiratory center has not been reactivated, hypoxia follows, and the cardiac rhythm will deteriorate into ventricular fibrillation. Research into the actual effects of lightning on humans is limited but it has been interestingly hypothesized that the strike leads to a state of suspended animation and cessation of metabolism in all cells, including the brain.3 This may explain reports of successful resuscitation and full recovery of lightning strike victims after being apneic and pulseless for 15 minutes and following resuscitations lasting up to 8 hours. This observation has led to the practice of treating the apparent dead first at the scene of a multiple-victim lightning strike because early resuscitative efforts may prevent death.

Myocardial contusion from the lightning shock wave is the most common pathologic finding. Myocardial infarction from prolonged hypoxia can occur. A variety of dysrhythmias may arise, generally resolving with time. A lightning strike in close proximity to a patient with an automatic implantable cardioverter defibrillator can cause firing of the device. A number of electrocardiographic changes, usually with gradual resolution, have been reported (Box 134.7).

Nervous System

A wide variety of very serious neurologic effects follow lightning strike. Apnea, due to effects on the medullary respiratory center, may persist for several hours. Direct trauma may result in skull fractures, intracerebral and extracerebral hematomas and hemorrhages, cerebral edema, and elevated intracranial pressure. More common findings include transient loss of consciousness, amnesia for the event, and transient paresthesias and paralysis of the extremities.3 Charcot, in 1889, described the phenomenon termed kerunnoparalysis, with the victim of a strike awakening to find himself or herself on the ground, unable to move the limbs. This flaccid paralysis, which is usually accompanied by marked vasmotor changes that result in extremities that appear blue, mottled, and pulseless, may persist up to 24 hours. The lower extremities are more commonly involved, and the typical pattern is recovery over minutes to days.

Prolonged loss of consciousness may be related to trauma or hypoxia. So-called miraculous recoveries have been documented, despite prolonged arrest and apnea. Conversely, death may occur rapidly from massive brain swelling and herniation. Permanent peripheral nerve damage can occur. Other neurologic sequelae include seizures, cerebellar ataxia, Horner’s syndrome, cognitive dysfunction, facial nerve palsy, neuritis, and neuralgia.

Some psychiatric effects are predictable, usually anxiety and a logical fear of thunderstorms. Other negative effects include prolonged depression, sleep disturbances, nightmares, nocturnal enuresis, and separation anxiety. Hysterical blindness, deafness, and muteness have been observed.

Skin

Roughly 90% of lightning strike victims suffer skin burns, but less than 5% are deep burns. Although the voltages involved in a strike are substantial, the duration of contact is so brief that significant damage does not usually occur. Skin resistance is typically lessened by rain or perspiration, contributing to the flashover effect, where current preferentially flows over the integument rather than through it (following the path of least resistance). The result is the arborescent or fernlike patterns of erythematous streaks (typically first-degree burns) that have been termed Lichtenberg figures (Fig. 134.4). Deeper burns may occur at the direct point of contact or wherever metal is involved (due to superheating), such as with a belt buckle or jewelry. Clothing may catch on fire, resulting in thermal burns. Unlike conventional high-voltage electrical exposures, exit wounds are not seen, and the overall effects are much less severe.
Lightning Injury

In cases in which lightning strikes are not witnessed, they may be suspected in patients presenting with altered mentation during thunderstorms in the presence of typical skin burn patterns or when their clothes have burst off, appear singed, or have punctate holes or metal pieces (zippers or grommets) that show signs of melting. Other suggestive findings are listed in Box 134.8. The differential diagnosis of altered mentation in lightning strike victims is the same as that of other high-voltage injuries.

DIAGNOSTIC TESTING

Electrical Injury

No evidence-based guidelines direct the ancillary testing of electrical injury victims. We believe that testing is not indicated for victims of low-voltage electrical injuries who are asymptomatic or have minimal localized symptoms and physical evidence of burn injury. Evaluation for underlying injury should be undertaken in patients who have been exposed to high-voltage sources and those who, regardless of the source voltage, have lost consciousness or present with altered mentation or neurologic deficits, other significant symptoms, entrance and exit wounds, and/or burns assessed as being more than superficial partial-thickness burns.

Because the location and extent of injury cannot be predicted clinically, we recommend electrocardiography, complete blood count, determination of basic serum electrolyte, serum myoglobin and troponin, blood urea nitrogen, and serum creatinine levels, renal function studies (blood urea nitrogen and creatinine), and urinalysis, with testing for myoglobin. Patients suspected of intra-abdominal injury from electrical current or associated trauma should have hepatic and pancreatic enzyme levels measured and coagulation studies performed. Radiographs of injured extremities are indicated; computed tomography or magnetic resonance imaging should be used when intracranial, spinal, intra-abdominal or pelvic injuries are clinically suspected.

Lightning Injury

The Wilderness Medical Society has recommended that an electrocardiogram (ECG) be obtained on lightning strike victims with high-risk indicators, such as suspected direct strike, loss of consciousness, focal neurologic complaint, chest pain or dyspnea, associated traumatic injuries, pregnancy, and burns of the cranium or legs or on more than 10% of the total body surface area. Cardiac markers are often elevated in victims of lightning strikes, but they do not correlate with myocardial injury and are not prognostic. Patients with altered mentation or symptoms and signs suggestive of traumatic injury should be evaluated...
thoroughly because of the massive shock wave and muscle spasm associated with lightning strikes. Complaints of diffuse muscle pain or findings of compartment syndrome should prompt evaluation for rhabdomyolysis and vascular sufficiency, bearing in mind that lightning has unique effects on the vascular system of extremities that often clear without sequelae.

**MANAGEMENT**

**Electrical Injury**

Low-voltage electrical injuries associated with minimal signs and symptoms generally require only local wound treatment and patient reassurance. The treatment of other patients is directed at the organ systems involved. Patients who present in cardiopulmonary arrest should be resuscitated, regardless of cardiac rhythm, because good outcomes have been documented in patients presenting in asystole. Patients with electrocardiographic signs of cardiac injury or dysrhythmias and patients with more than minimal local signs and symptoms should be monitored in the emergency department (ED), observation unit, or inpatient setting, depending on the extent and severity of associated injuries. Dysrhythmias are treated according to advanced cardiovascular life support (ACLS) guidelines. Hypotension may be caused by third spacing of intravascular volume secondary to electrical injury of deep tissues, so fluid management is similar to that of crush injuries, often requiring much more fluid than typically recommended by thermal burn wound protocols. Intravenous crystalloid fluids are given to maintain adequate urine output: over 100 mL/hr in adults and 1.5 to 2 mL/kg/hr in young children. Serum potassium levels should be closely monitored in patients with renal insufficiency or myoglobinuria. Importantly, hypotensive patients should be evaluated for possible blood loss from associated traumatic injuries.

Patients with myoglobinuria should be monitored with determination of serial serum myoglobin levels and renal function studies. The management of rhabdomyolysis is discussed in Chapter 119.

Injured extremities require burn wound management (see Chapter 56). They should be monitored for the development of compartment syndromes (see Chapter 42).

Patients injured by CEWs rarely need intervention or ancillary testing. Retained barbs can be removed with firm in-line traction.

**Lightning Injury**

Lightning strike victims who present without symptoms or signs of injury, including those with minor first-degree burns (see Fig. 134.4), do not require treatment in the ED unless their electrocardiograms show signs of ischemia or significant dysrhythmias.

Patients who present with altered mentation or significant symptoms are approached in a manner similar to that used for victims of high-voltage electrical injury. However, a few differences should be noted. Lightning strikes can result in a spectrum of peripheral and central neurologic injuries, including pupils that are dilated and fixed in the absence of irreversible brain injury. This factor should be kept in mind when deciding when to discontinue resuscitative efforts in patients who present in cardiac arrest. Lightning strikes can cause extensive catecholamine release or autonomic stimulation, resulting in transient hypertension and tachycardia that can be treated with β-adrenergic blockers and hydralazine or with alpha blockers, such as clonidine, to reduce adrenergic excesses.

Although AC causes thrombotic injury to blood vessels, DC can result in transient vasospasm that results in extremities that appear blue, mottled, and pulseless. This should be kept in mind when deciding when surgical intervention is indicated. Skin and vascular findings are likely to resolve with supportive care only but, if significant thrombosis (immediate or delayed) develops, amputation may be required. The presence of pulseless and mottled extremities may limit the ability to detect hypotension with basic tools, and central monitoring lines may be required to assess volume status correctly.

**DISPOSITION**

**Electric Injury**

Asymptomatic patients who present after low-voltage exposures may be safely discharged. Other patients will be monitored and treated in the ED, observation unit, or inpatient setting, depending on their clinical status and extent and severity of identified injuries. Patients with significant burns should be stabilized and transferred to a burn unit, if available.

Pediatric patients with oral electric injuries are usually hospitalized for hydration, wound and pain management, and plastic surgery consultation. Patients with minor burns confined to the oral commissure can be discharged with close follow-up but should be provided with information regarding the possibility of delayed labial artery bleeding, which can be managed by the parents with direct pressure and a return visit to the ED.

Pregnant patients should receive a period of fetal monitoring when age-appropriate. Women who are subsequently discharged should be counselled regarding the remote risk of spontaneous abortion and referred for high-risk obstetric follow up. Patients may experience delayed neuropsychiatric sequelae, so discharge instructions regarding this possibility should be provided.

**Lightning Injury**

The Wilderness Medical Society has recommended that victims of direct lightning strikes and those with an abnormal ECG be monitored with telemetry for a minimum of 24 hours. Other patients can be discharged but should be counselled regarding the need to seek further care if they develop delayed-onset symptoms, which can be cardiopulmonary, neurologic, psychiatric, ophthalmologic, or otolaryngologic in nature.
Electrical current follows the path of least resistance, often neurovascular bundles. Deep tissue and organ damage is often much more extensive than would be indicated by examination of the overlying skin.

Testing is not indicated for victims of low-voltage electrical injuries who are asymptomatic or have minimal local symptoms and physical evidence of burn injury. These patients may be discharged home after evaluation.

Testing is indicated for patients exposed to high-voltage sources and those with syncope, altered mentation, or any other neurologic abnormality, significant burns, entry and exit wounds, or significant ongoing symptoms. Testing should include electrocardiography, complete blood count, basic chemistry panel, myoglobin and troponin level determination, and urinalysis. Additional testing is directed at suspected areas or injuries.

Patients with electrocardiographic signs of cardiac injury or dysrhythmias, or with evidence of significant local injury, should be monitored for at least 6 hours in the ED, observation unit, or inpatient setting.

The enormous current of a lightning strike may cause critical injury or death, or the current may be directed superficially over the patient to the ground, resulting in no injury or only superficial burns.

Electrocardiography is indicated for all patients evaluated for lightning strike. Additional testing should be based on specific signs and symptoms.

Lightning strike patients who present without symptoms or signs of injury, or with only minor first-degree burns, and with a normal ECG can be discharged home after evaluation. Patients who present with altered mentation or significant symptoms are evaluated in a manner similar to that used for victims of high-voltage electrical injury.

Lightning strike can cause fixed, dilated pupils in the absence of irreversible brain injury.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
134.1. A man walking through a park after a storm accidentally steps on a downed electrical wire and is rendered unconscious. Before rescuing him, how can prehospital providers ensure their own safety and that of bystanders? 
A. Call the power company to disconnect the power.
B. Loop a leather belt around the wire to move it.
C. Use a dry rope to loop around the wire and pull it away from the victim.
D. Use a tree branch or piece of wood, such as a 2 by 4, to move the wire.
E. Use electrical gloves to move the wire manually.

Answer: A. The prime tenet of rescue work is create no further complications. The only safe and reliable way to ensure that the power is off is to notify the power company to have the power turned off. None of the other choices is safe, and they could result in severe injury to the rescuer using them.

134.2. A 37-year-old woman presents with blurred vision. Her vision has been progressively worsening for approximately 2 months. She denies eye pain or direct eye trauma. She reports that approximately 2 months ago, just before the beginning of her vision problems, she was struck by lightning while playing golf. She states that she went to an emergency department (ED) at that time, had no major injuries, and seems to have recovered well. What is the most likely cause of her decreased vision? 
A. Cataracts
B. Glaucoma
C. Iritis
D. Macular degeneration
E. Retinal detachment

Answer: A. Cataracts are a well-known complication of electrical injury, either from artificial electrical sources or from lightning. They may occur immediately or have a delayed presentation. Approximately 6% of victims of electrical injury develop cataracts. Glaucoma is due to elevated intraocular pressure and is often painful. Iritis and retinal detachment can be caused by electrical injury but are manifested acutely. Macular degeneration is a chronic condition of older adults with central vision loss and is not associated with electrical injury. Macular holes may occur acutely with lightning injury.

134.3. A 42-year-old man suffers an electrical injury while working on power transmission lines near your hospital. Paramedics report that he is unresponsive and that he was initially in ventricular fibrillation but spontaneously converted to sinus tachycardia before treatment. His initial electrocardiogram (ECG) from the field shows ST segment elevation in the inferior leads. An ECG repeated in the ED shows continued inferior ST segment elevation but with decreased magnitude. Creatine kinase (CK) and CK-MB levels are markedly elevated. He continues to be unresponsive, has no spontaneous respirations, and has bilateral fixed and dilated pupils. What is the appropriate next action? 
A. Brain death testing
B. Cardiac catheterization
C. Mannitol infusion
D. Observation and supportive care
E. Thrombolytic administration

Answer: D. Electrical injury can cause a variety of cardiac manifestations, including multiple dysrhythmias, transient ST elevation, and conduction blocks. Myocardial infarction, although reported, is rare. Extensive skeletal muscle damage can be seen in electrical injuries and results in marked elevations of CK and CK-MB levels. Respiratory muscle paralysis and ocular injuries often occur. This patient is probably not brain-dead, nor has he suffered a myocardial infarction. Mannitol is used in cases of impending cerebral herniation, which is not expected in this patient.

134.4. A 3-year-old boy is brought to the ED by his parents after burning his mouth while chewing on an electrical cord. He has partial-thickness burns to the left side of his upper and lower lips and an oral commissure. What complication of this injury needs to be considered in planning patient treatment and disposition? 
A. Cardiac dysrhythmias
B. Cataracts
C. Contractures involving the orbicularis oris muscle
D. Delayed labial artery bleeding
E. Rhabdomyolysis

Answer: D. When the initial eschar separates, there is risk of exposure of the labial artery, with resultant significant arterial bleeding. Traditionally, admission for observation has been advocated for these patients but, if there is good social support, discharge with specific instructions and close follow-up are appropriate. These types of electrical injury have only local effects, so dysrhythmias, cataracts, and rhabdomyolysis are not complications. Contractures are common and may require reconstructive surgery, but this complication is not life-threatening.

134.5. You are camping with a group of five students. A sudden thunderstorm arises and lightning strikes your camp. You are uninjured, but all five students are injured and are lying on the ground. Their conditions are described here.
You are the only person available to provide medical support. After quickly calling 911, which student should receive your primary attention?

A. Student A is unconscious and has no spontaneous respirations, an irregular pulse, and no obvious injuries.
B. Student B is unconscious and has spontaneous respirations, a rapid and faint pulse, and no obvious injuries.
C. Student C is conscious, is screaming in pain, and has an easily palpable pulse an obvious open femur fracture after being thrown against a tree.
D. Student D is conscious, is screaming in pain and has an easily palpable pulse and obvious second- to third-degree burns involving his face, left arm, and left leg.
E. Student E is conscious, is talking rapidly, has an easily palpable pulse, and complains of complete blindness.

**Answer:** A. This student has suffered respiratory arrest. Unlike in traditional mass casualty triage guidelines, patients without spontaneous respirations take first priority. Lightning frequently causes complete cardiopulmonary arrest, but cardiac automaticity often returns spontaneously. However, respiratory muscle paralysis can persist for several minutes. If patients are adequately ventilated during this time, prognosis for recovery is excellent. Student B may have a dysrhythmia or internal injuries causing shock. Although both conditions are potentially serious, there is little that a single rescuer in the field can do. Patients without cardiopulmonary arrest rarely die in the field.

**134.6.** A 29-year-old man is brought to the ED after a reported lightning strike. He is unresponsive and has been intubated before arrival by emergency medical services. The monitor reveals a sinus tachycardia at a rate of 125 beats/min, and his blood pressure is 196/118 mm Hg. Pupils are fixed and dilated. The lower extremities are cool and mottled, with absent pulses in the feet. Which of the following is the most appropriate for managing the patient?

A. Begin heparin, order lower extremity angiography, and consult vascular surgery.
B. Consult neurosurgery for determination of brain death.
C. Initiate treatment for hypertension with a titratable intravenously infused beta blocker.
D. Obtain a computed tomography (CT) scan of the head.

**Answer:** D. Nonreactive pupils are not a reliable method of determining neurologic status immediately after lightning injury. Vasospasm may result in pulseless mottled extremities but usually resolves spontaneously within a few hours. Similarly, hypertension is common and should not be treated initially. Any patient with loss of consciousness or persistent neurologic impairment should have CT scanning of the head to rule out an intracranial anatomic cause.
PRINCIPLES

Background

Underwater free diving to salvage wrecks and to harvest seafood, sponges, coral, and mother-of-pearl has been practiced for more than 5000 years. The earliest artificial underwater breathing devices, hollow tubes, were impossible to use at depths greater than 3 feet because of restricted inspiration caused by the pressure of the water. However, subsequent inventions in the sixteenth to the nineteenth centuries allowed dives to greater depths.

With the advent of these technologies, the symptoms of diving-related illness, also known as dysbarisms, began to be recognized. Colonel William Pasley, the officer in charge of a unit of the British Royal Engineers that salvaged the sunken warship HMS Royal George in 1840, observed symptoms in his divers. At approximately the same time, similar symptoms and even fatalities were observed among caisson workers. The ailment became known as caisson disease, but the construction workers on the Brooklyn Bridge (built from 1870 to 1883) called it “the bends,” because the symptoms often caused the victim to bend forward in pain. The first clinical description was by Paul Bert in 1878. He correctly attributed the disease to nitrogen gas coming out of solution in the tissues during decompression leading to the recommendation of slow ascents for pressurized workers and the development of the first recompression chambers.

The breakthrough that allowed more widespread adoption of diving at depth was the invention of the aqua-lung by Jacques-Yves Cousteau and Emile Gagnan in 1943. The lighter and less expensive equipment, widely known by its acronym SCUBA (self-contained underwater breathing apparatus), does not require a surface supply of air or the support personnel that are necessary for helmet diving. Millions of divers have become certified to date.

Most amateur divers use compressed air, open-circuit scuba equipment at depths of less than 130 feet of seawater (fsw). Systems with artificial mixtures of various gases, however, are used to extend the depths to which divers can descend or the duration that a diver may safely remain submerged (“bottom time”).

Other variations of supplying air for divers are closed-circuit and semiclosed-circuit diving apparati (“rebreathers”) that use calcium hydroxide to absorb expired carbon dioxide. Oxygen is then added to the decarboxylated gas before rebreathing. The advantages of rebreathers over compressed air scuba are that they are more efficient (less gas is used for a given time), allow deeper dives and longer bottom times, and generate few if any bubbles. However, approximately three injuries of any kind happen per 100 dives based upon a 2011 survey performed by the Diver Area Network. Divers experience decompression-related illnesses, one of the most serious dive-related injuries, in 1.55 dives per 1000. Although the rate of patients experiencing decompression illness has remained relatively constant, the absolute numbers have increased with the ever growing number of certified divers and dives being performed.

Pathophysiology

Scuba divers may encounter emergencies common to environmental exposures (eg, hypothermia, sunburn, and physical trauma) or aquatic activities (eg, submersion accidents, motion sickness, and marine envenomations), but they are also subject to the unique injuries related to dysbarisms and barotrauma. The pathophysiologic mechanism of dysbarisms and barotrauma primarily results from volume-pressure changes within the air-filled cavities of the body or from increased dissolution of gases, particularly nitrogen, in body tissues.

Atmospheric pressure varies with altitude and weather patterns, but 760 mm Hg (14.7 psi or 1 atm) is the standard used at sea level. Water is far denser than air. A mountain climber would need to ascend to 18,000 feet to reduce atmospheric pressure by 50% from sea level, but a diver needs to descend only 33 feet in seawater (34 feet in fresh water) to double the atmospheric pressure, an increase of 23 mm Hg per foot of depth. It is for this reason that it is extremely uncommon to see dysbarisms related to altitude changes except in military aircraft pilots or in the rare instance of sudden depressurization of an airliner.

To understand the pathophysiologic processes of dysbarisms and barotrauma, one should be familiar with several of the laws of physics that define the behavior of liquids and gases (Table 135.1; Figs. 135.1 to 135.5). The human body is composed mostly of water and behaves like a liquid subject to Pascal’s law, which states that a pressure applied to any part of a liquid is transmitted equally throughout. Pressure changes, however, do alter the volume within the air-filled spaces of the body, including the lungs, bowel, sinuses, and middle ear, according to Boyle’s law. This law states that at constant temperature, the absolute pressure and the volume of gas are inversely proportional (PV = k). In other words, as pressure increases (with descent), the gas volume is reduced; as the pressure is reduced (with ascent), the gas volume increases.

Temperature also affects the pressure and volume of a gas as described by Charles’ law. At a constant pressure, the volume of a gas is directly proportional to the change in the absolute temperature (V1/T1 = V2/T2). Thus, with heat the volume increases, and with cold the volume decreases. The general gas law (PV = k) combines Boyle’s and Charles’ laws to predict the behavior of a given quantity of gas when any of these factors change.

Barotrauma results when a diver is unable to equalize the pressure within air-filled structures to the ambient pressure of the environment during ascent or descent. Fractional changes in volume are greater near the surface. Thus the greatest risk for barotrauma is in shallow water, where the proportional pressure changes are also the greatest.

Dalton’s law states that the total pressure exerted by a mixture of gases is equal to the sum of the pressures (partial pressures) of

---

*Caissons are construction chambers filled with pressurized air that permit working in a dry environment. They have been used in the construction of bridge footings and tunnels in places that would otherwise have been underwater.
component gas of the inhaled air will dissolve in solution until a new steady-state concentration is achieved.

The length of time the diver is breathing the gas at the increased pressure and the inherent solubility of the gas also govern the quantity of a particular gas that dissolves. As the diver ascends, however, increasingly more of the dissolved gas comes out of solution. A rapid ascent may reduce the pressure at a rate higher than the body can accommodate, and the bubbles (particularly nitrogen) may accumulate and disrupt body tissues and systems, a phenomenon termed decompression sickness (DCS). This is similar to the way that rapid opening of a bottle of soda allows bubbles of carbon dioxide to come out of solution rapidly.

If the ascent rate is controlled (ie, through the use of the safe decompression tables or submersible dive computers), the gas is carried to the lung vascular bed and is exhaled before it accumulates to form significantly large or numerous bubbles in the tissues, similar to how opening of a soda bottle slowly reduces the bubbling of the contained carbonated liquid.

**CLINICAL FEATURES**

The clinical features of the injuries and illnesses related to diving will be presented in this section based on when the symptoms are
likely to start during a dive, first those that occur on descent, then those that occur at depth, and finally those that occur upon surfacing. This organization is used to help the clinician stratify the likelihood of a specific disorder based on when the symptoms started during the dive. Box 135.1 lists the components of a focused dive history.

**Disorders Related to Descent**

**Middle Ear Barotrauma**

Middle ear barotrauma (MEBT), also known as barotitis or ear squeeze, is the most common complaint of scuba divers. It is experienced by approximately 30% of novice scuba divers and 10% of experienced divers. The middle ear is an air-filled space with solid bone walls except for the tympanic membrane (Fig. 135.6). The eustachian tube is the only anatomic passage to the external environment.

As the diver descends, the water exerts increasing pressure against the intact tympanic membrane. Typically, the diver performs various maneuvers to force air into the middle ear through the eustachian tubes in an attempt to maintain equal pressure across the tympanic membrane. If the diver fails, the floppy medial third of the eustachian tube collapses shut, making any further attempts at equalization futile. This is typically painful and can be associated with tinnitus; some patients develop transient vertigo.

Bird caused

Fig. 135.6. Middle ear barotrauma symptoms include fullness and pain caused by stretching of the tympanic membrane. (From Van Hoesen KB, Bird NH: Diving medicine. In Auerbach PS, ed: Wilderness medicine, ed 6, Philadelphia, 2012, Elsevier, p 1529.)

BOX 135.1

Focused Dive History

When was the first onset of symptoms?
What type of equipment was used? Compressed air, mixed gas, enriched air, rebreather? What was the source of the gas?
Did the dive approach or exceed decompression limits? Was a dive computer used?
What were the number, depth, bottom time, total time, and surface intervals for all dives in the 72 hours preceding symptoms (the dive "profiles")?
Were decompression stops used? Was in-water decompression attempted?
What was the time delay from the last dive to air travel?
Did the dive experience difficulty with ear or sinus equilibration? Did the pain occur on descent or ascent?
Was the diver intoxicated? Dehydrated? Working strenuously?
How long after the dive did symptoms present? Were they present at surfacing? Delayed? Progressive?
Is a medical history of ear or sinus infections or abnormalities present?
Emphysema or asthma? Coronary artery disease? Patent foramen ovale (PFO)? Neurologic illness?

Further descent without successful equalization can cause the tympanic membrane to rupture. The pain may or may not resolve as the tympanic membrane ruptures. The ruptured tympanic membrane can cause caloric stimulation by exposure of the middle ear to cold water, inducing a transient nystagmus and vertigo. The pressure of the water in the middle ear may lead to a facial palsy in certain individuals where the seventh cranial nerve passes unexposed through this space. On occasion, this disorder can be life-threatening during a dive as the subject becomes disoriented and can drown.

External Ear Barotrauma

External ear barotrauma is less common than MEBT and results from the outward bulging of the tympanic membrane during descent. Normally, the external auditory canal is filled with water during descent; however, obstruction of the external auditory canal for any reason (eg, cerumen, stenosis, earplugs, or a tight-fitting wet suit hood) can trap air, causing a relative negative pressure. This may lead to localized pain and/or hemorrhages in the wall of the external auditory canal on examination. These symptoms are typically self-limited.

Inner Ear Barotrauma

Inner ear barotrauma (IEBT) results in damage to the cochleoves-tibular apparatus. It is much less common than MEBT but is associated with greater morbidity. A large negative pressure gradient develops in the middle ear if the diver is unable to equalize pressure during descent, similar to MEBT. Inward deflection of the tympanic membrane is transmitted to the oval window of the cochlea, which causes an outward distention of the round window into the middle ear. Sudden equilibration of pressure in the middle ear or a vigorous Valsalva maneuver may rupture the round window, lead to hemorrhage into the inner ear, or tear the labyrinthine (Reissner’s) membrane.

Symptoms associated with IEBT include variable hearing loss, severe vertigo, nausea, tinnitus, and fullness in the affected ear. Signs include severe nystagmus, positional vertigo, ataxia, and vomiting. The degree of sensorineural hearing loss is variable. Distinguishing IEBT from inner ear DCS can be challenging but should not delay recompression in a patient in whom the diagnosis is in doubt.

Barosinusitis

Obstruction of the sinus ostia for any reason (eg, mucosal thickening, polyps, pus, or deviated septum) predisposes to sinus barotrauma, the second most common complaint among divers. The air-filled maxillary, frontal, and ethmoidal sinuses are susceptible to volume-pressure changes on ascent or descent; the most commonly affected is the maxillary sinus, followed by the frontal. The most common symptoms are facial pain and epistaxis.

Facial Barotrauma

As water pressure increases during descent, a negative pressure develops within the dive mask over the eyes and nose, which must be equalized by forced exhalation through the nose. When this is not adequately performed, the large negative pressure gradient may lead to facial and conjunctival edema, diffuse petechial hemorrhages on the face, and subconjunctival hemorrhages. Very rarely, optic nerve damage can result from severe facial barotrauma.

Disorders Arising at Depth

Nitrogen Narcosis

Nitrogen narcosis, known as rapture of the deep, results from the intoxicating effects of increased tissue nitrogen concentration at depth. Symptoms include euphoria, false feeling of well-being, confusion, loss of judgment or skill, disorientation, inappropriate laughter, diminished motor control, and tingling and vague numbness of the lips, gums, and legs. With breathing of compressed air, symptoms typically begin to occur at approximately
100 feet and often become profound at depths of more than 150 feet. Because of these dangers, the use of compressed air is not recommended and instead mixed gases with a lower concentration of nitrogen are suggested for sport diving to depths of more than 120 feet. Although the effects of nitrogen narcosis resolve with ascent to shallower depths and are variable between individuals, the diver may drown because of poor judgment or seriously impaired motor skills in the presence of a dive emergency.

**Oxygen Toxicity**

At elevated partial pressures for extended periods, oxygen can be toxic to the central nervous system (CNS) or lungs. Oxygen becomes toxic to the CNS when its partial pressure exceeds 1.6 atmosphere absolute (ata). Oxygen partial pressures below 1.4 ata are unlikely to produce CNS toxicity. A diver breathing compressed air would attain a partial pressure of 1.6 ata of oxygen at a depth of 218 fsw. This far exceeds the depth to which sport divers would go. Deep divers prevent oxygen toxicity by breathing mixed gases with decreased oxygen content (eg, hypoxic trimix).

Pulmonary oxygen toxicity (low-pressure oxygen poisoning) can occur after 24 hours of exposure to partial pressures of oxygen in excess of 0.6 ata. The symptoms of pulmonary oxygen toxicity include a burning sensation or pain on inspiration and coughing. Pulmonary function gradually becomes normal after the exposure is terminated, but pneumonitis and permanent fibrosis are possible. It is extremely unlikely that a sport diver would ever be exposed for the duration that is required to produce toxicity; however, long exposures to higher levels of oxygen, such as those administered for certain recompression protocols, may lead to pulmonary oxygen toxicity.

**Contaminated Air**

Rarely, other gases, such as carbon monoxide and carbon dioxide, can contaminate the air that is compressed into a tank. This can happen, for example, if the compressor intake is located too close to the compressor’s engine exhaust. As in the case of oxygen and nitrogen, the partial pressure of these contaminants in the tissues increases dramatically with depth, potentiating their clinical effects. The symptoms of hypercarbia or carbon monoxide poisoning are more severe at elevated partial pressures. Hypercarbia increases a diver’s susceptibility to CNS oxygen toxicity.

Rebreathers release microscopic calcium hydroxide or “soda lime” dust particles into the apparatus. These particles are small enough and have geometric characteristics that allow them to be deposited in the alveoli. When soda lime comes into contact with water, it forms a caustic liquid. In the event of a hose rupture allowing seawater contamination of the circuit, caustic burns to the mouth, throat, and airways may result. Chronic exposure to soda lime dust may contribute to long-term effects on respiratory function.

**Disorders Arising on Ascent**

**Alternobaric Vertigo**

Alternobaric vertigo (ABV) results from an inability to equalize pressure within the middle ear during ascent. Although equalization during descent requires active maneuvers to maintain eustachian tube patency, air normally exits the middle ear without difficulty during ascent because the pressure within the middle ear exceeds ambient pressure. In the setting of mucosal edema or thickening within the eustachian tube, however, the passage of air may be impeded. The problem is typically unilateral. When the pressure gradient within the middle ear reaches 60 cm H₂O, increased labyrinthine discharge produces nystagmus. Clinically, the patient experiences a profound but transient sense of vertigo during ascent that may be associated with nausea and vomiting. Unlike those of IEBT, the symptoms are self-limited.

**Barodontalgia**

On occasion, air that is trapped beneath a poorly filled dental cavity or within a dental abscess expands on ascent, leading to dental pain. This condition is relatively benign and self-limited.

**Gastrointestinal Barotrauma**

Serious gastrointestinal barotrauma is a rare condition in scuba divers. It results from the expansion of bowel gas in the small intestine and colon on ascent after diving. Predisposing factors include consumption of carbonated beverages, large meals, or gas-producing foods before diving, as well as performance of the Valsalva maneuver in the head-down position. Symptoms include eructation, flatulence, bloating, and crampy abdominal pain. In divers with inguinal or other hernias, the potential for expansion of trapped gas within the hernia exists, and expansion may result in incarceration or strangulation. Gastric rupture is a rare complication. Although gastrointestinal barotrauma is a rare entity, it should be suspected in the diver-patient with a provocative history and abdominal pain.

**Pulmonary Barotrauma**

Without continuously expiring on ascent, the lungs of a scuba diver who takes a full breath at 33 fsw would have to expand to double their volume by the time they reached the surface (Boyle’s law). However, the expansion of the alveoli is limited. The increase in pressure either forces gas bubbles across the alveolar-capillary membrane or causes the wall of the alveoli to rupture. A change in depth of 3 to 4 feet (or pressure difference of 80 mm Hg) is all that is required to force air bubbles across the alveolar-capillary membrane.

In fact, the greatest risk for pulmonary barotrauma occurs in less than 10 feet of water. Therefore, it is important for the clinician to consider this disease entity in patients with consistent symptoms even after exposure to shallow depths. Pulmonary barotrauma can result in the following four conditions: pneumothorax, pneumomediastinum, subcutaneous emphysema, and alveolar hemorrhage. Risk factors elicited from the dive and medical history may suggest the diagnosis of pulmonary barotrauma. In most cases, fast ascent, panic, problems in regulating buoyancy, or running out of air is noted.

Patients with restrictive and obstructive lung diseases are at particular risk. Asthmatics have a twofold-increased risk for pulmonary barotrauma compared with the general diver population. Box 135.2 lists six mechanisms that contribute to the increased risk in asthmatics.

Asthma severity can wax and wane. Because symptoms may worsen for 4 to 6 weeks after an upper respiratory infection or during certain seasons, asthmatics should refrain from diving until they are completely free of symptoms. Box 135.3 summarizes the recommendations from the multiple national scuba governing agencies, as well as expert consensus.

Pneumomediastinum and subcutaneous emphysema result when air crosses the alveolar endothelium and dissect into the pulmonary interstitium. Most commonly, the air then travels into the neck, mediastinum, or pericardium. The manifestations of pneumomediastinum may include fullness in the neck, palpable subcutaneous crepitance, and a change in voice quality or timbre. Unless evidence of either hemodynamic instability or airway compromise exists, interstitial air or subcutaneous emphysema is not a life-threatening condition.
Pneumothorax may occur when the air that escapes from alveoli as a result of pulmonary barotrauma crosses the visceral pleura. A tension pneumothorax is a rare complication. The symptoms and signs of a pneumothorax secondary to pulmonary barotrauma are typical for a pneumothorax of any cause. Pulmonary barotrauma can also cause alveolar hemorrhage. Patients may present with hemoptysis coincident with chest pain and dyspnea. Chest radiography may reveal an interstitial infiltrate.

Decompression Sickness

The term *decompression sickness* (DCS) refers to a spectrum of clinical illnesses resulting from the formation of small bubbles of nitrogen gas in the blood and tissues on ascent. The clinical expression of DCS depends on the location, destination, and degree of nitrogen bubble formation in blood and tissues. Small, asymptomatic venous gas emboli are common in the ascending diver and are filtered by the lungs without apparent permanent damage. Persistent intravascular bubbles, however, elicit inflammatory cascades, cytokines, the complement system, platelet aggregation, and thrombosis. Furthermore, the bubbles can cause mechanical obstruction, ischemia, and tissue hypoxia. Nitrogen is highly fat soluble, and the heavily myelinated white matter of the CNS is at particular risk for DCS.

The incidence of DCS is estimated to be 1.55 per 1000 dives based upon self-reporting; however, some divers may fail to present to a health care professional. The potential for development of DCS increases with the length and depth of a dive. Other risk factors include age, obesity, fatigue, heavy exertion, dehydration, fever, cold ambient temperatures after diving, diving at high altitude, and flying after diving. Tobacco and ethanol use may also increase susceptibility to DCS. The risk of DCS is 2.6 times greater for men than for women, possibly due to risk-taking behaviors. There appears to be no increase in DCS in women who are taking oral contraceptive agents or menstruating during diving.

A patent foramen ovale (PFO) is a risk factor for increased susceptibility to DCS. Sixty-five percent of divers who present with serious DCS have a PFO. Brain lesions occur in 27% of all sport divers. This percentage is roughly the same as the prevalence of PFO or other right-to-left shunts in the general population. These multiple brain lesions may be caused by bubbles in the venous circulation that are not filtered by the vasculature of the lungs but enter the arterial circulation, even in the absence of other DCS symptoms. Most sport divers do not undergo screening for PFO with echocardiographic bubble studies; some PFOs may open only at increased ambient pressures so that bubble studies conducted at 1 ata might be normal.

The United States Navy dive tables estimate the amount of nitrogen that accumulates in the body during a dive to a particular depth and duration. The tables calculate a maximal dive time, called the *no-decompression limit*. If the no-decompression limits are exceeded, underwater decompression stops are recommended. Many sport scuba divers use submersible dive computers to calculate maximum dive times in lieu of the tables. These tables and computers are meant to reduce the likelihood of exceeding the solubility of nitrogen at sea level to produce DCS. The diver still must ascend in a slow, controlled manner to allow the gradual release of nitrogen. Off-gassing continues after the diver has surfaced. Repetitive dives within several hours result in accumulation of tissue nitrogen and shorter no-decompression limits. Because dive tables are based on several assumptions about nitrogen elimination, even strict adherence to these tables does not guarantee that DCS will not occur. The risk of DCS increases as a diver approaches the no-decompression time limits. DCS typically is manifested within hours after surfacing. Approximately 40% of symptoms occur within 1 hour after diving, 60% within 3 hours, 80% within 8 hours, and 98% within 24 hours. In a recent review of 5278 cases of DCS at a single hyperbaric unit more than 98% had symptoms within 6 hours and the mean time to symptom onset was 62 minutes. Flying shortly after diving or ascending to altitude, however, may cause symptoms in patients later than expected, and some patients present days after diving with DCS.

Traditionally, DCS has been divided into two categories, type I and type II. Type I DCS affects the musculoskeletal system, skin, and lymphatic vessels. Type II DCS involves any other organ system. The more inclusive “decompression-related illness” is now also used to encompass DCS I, DCS II, and arterial gas embolism (AGE). This terminology is adapted to aid clinicians in remembering that the distinction is irrelevant in the selection of treatment. All types of decompression illness require recompression. DCS I, DCS II, and AGE can coexist. The symptoms of DCS may be subtle and resolve by the time of evaluation. A distribution of the most common symptoms and the first symptoms is presented in Figure 135.7.

Type I DCS can be experienced as variable and periarticular pain in the arms and legs. The elbow and shoulder joints are most commonly affected. Local tenderness and erythema are uncommon. The placement of a blood pressure cuff inflated to 150 to
decompression illness because of its high lipid content. The spinal cord, especially the upper lumbar area, is more often involved than cerebral tissue. Symptoms of spinal DCS include limb weakness or paralysis, paresthesias, numbness, and low back and abdominal pain. Limb symptoms often begin as a distal prickly sensation that advances proximally, followed by progressive sensory or motor loss. A dermatome sensory level occurs in some spinal DCS patients, often at the T12 to L1 dermatomes. Bladder symptoms, fecal incontinence, and priapism may occur. Unlike patients with spinal cord trauma, patients experiencing DCS may have patchy or unequally distributed sensory and motor findings.

Spinal DCS can occur alone or in combination with cerebral, inner ear, or pulmonary symptoms. Cerebral symptoms include mild to moderate headache, blurred vision, diplopia, dysarthria, unusual fatigue, inappropriate behavior, and a sense of detachment. Loss of consciousness in CNS DCS is rare (in marked contrast to AGE).

Inner ear DCS is commonly called the "staggers." Approximately 24% to 36% of patients that present with DCS report cochlear vestibular symptoms. The symptoms of inner ear DCS are the same as those of IEBT and include nausea, dizziness, vertigo, nystagmus, and hearing loss. The most common symptoms are vestibular in nature with only 25% of patients exhibiting hear loss or tinnitus. This can usually be distinguished from IEBT because the onset happens during ascent or after surfacing.

Pulmonary DCS is called the "chokes." All divers are exposed to some degree of microbubble emboli to the lungs on ascent. The progression to symptoms depends on the number and volume of bubbles. The deposition of venous gas emboli in the pulmonary arterial circulation produces progressive dyspnea,

Fig. 135.7. Classification of initial and of all eventual manifestations of decompression illness in 2346 recreational diving accidents reported to the Divers Alert Network (DAN) from 1998 to 2004. *For all instances of pain, 58% consisted of joint pain, 35% muscle pain, and 7% girdle pain. Girdle pain often portends spinal cord involvement. †Constitutional symptoms included headache, lightheadedness, inappropriate fatigue, malaise, nausea or vomiting, and anorexia. ‡Muscular discomfort included stiffness, pressure, cramps, and spasm but excluded pain. §Pulmonary manifestations included dyspnea and cough. (From Vann RD, Butler FK, Mitchell SJ, et al: Decompression illness. Lancet 377:153-164, 2011.)

Arterial Gas Embolism

AGE results when air bubbles are forced across the alveolar-capillary membrane, escape into the pulmonary venous circulation, and proceed through the left atrium and ventricle into the arterial circulation. It is one of the most common causes of death in divers. Clinical symptoms and signs are in part the result of mechanical obstruction by gas bubbles. AGE can also result from a right-to-left shunt of venous bubbles, such as in a diver with a PFO. AGE may occur alone or in conjunction with DCS.

Although air bubbles may embolize to any organ, the coronary and cerebral arteries are associated with the most serious consequences. Emboli to the coronary arteries may cause cardiac ischemia, myocardial infarction, dysrhythmias, or cardiac arrest. Dysrhythmias are also indirectly caused by centrally mediated autonomic dysfunction from cerebral emboli. Mechanical occlusion of the cerebral vasculature from emboli, most commonly to the anterior and middle cerebral arteries, causes a variety of symptoms and signs similar in appearance to an acute stroke. Large volumes of gas can lead to cardiac “vapor lock” where the intracardiac bubbles mechanically displace blood in the ventricles leading to a precipitous fall in cardiac output with resultant hypotension or even death.

The clinical manifestations of AGE may be sudden, dramatic, and life-threatening. Divers who have supposedly “drowned” may actually have lost consciousness during ascent as a result of cerebral gas emboli. Any diver breathing compressed air at any depth underwater and who surfaces unconscious or who loses consciousness within 10 minutes of reaching the surface should be assumed to be suffering from AGE. The most common presentation of AGE includes a global alteration of consciousness, headache, dizziness, convulsions, and visual changes. Other common presenting symptoms and signs include cranial nerve symptoms, unilateral weakness, unilateral or bilateral sensory loss, ataxia, and speech changes. Pulmonary symptoms, including dyspnea, pleuritic chest pain, and hemothysis, occur in 25% to 50% of cases.

Pulmonary Edema

Pulmonary edema while scuba diving was first reported in the 1980s. An increase in afterload (from vascular hyper-reactivity, possibly triggered by cold) combined with an increase in preload (from the hyperbaric underwater environment) may be the cause.

DIFFERENTIAL DIAGNOSES

Most diving injuries have limited differential diagnoses that include medical disorders and trauma unrelated to dysbarism. The differential diagnosis of IEBT includes inner ear DCS, ABV, and isolated MEBT with a rupture of the tympanic membrane. It is relatively easy to distinguish IEBT from MEBT and ABV because the vestibular symptoms associated with the last two entities are transient and self-limited (Table 135.2). When IEBT occurs simultaneously with MEBT, the presence of both may be documented by an audiogram, which demonstrates both a conductive and a sensorineural hearing loss.

The differentiation of IEBT from inner ear neurologic DCS is crucial because the treatments differ. An IEBT is more likely when symptoms begin during descent or the diver relates a history of difficulty equilibrating or performing a vigorous Valsalva maneuver. If the dive profile is examined and the no-decompression limits are approached and symptoms began soon after surfacing, inner ear DCS is more likely. A history of difficulty in equalizing the ears on descent, or the onset of symptoms early in the dive, suggests barotrauma. A history of a dive that approaches decompression limits, or the onset of symptoms during or soon after ascent, and the presence of other neurologic findings suggest DCS. A trial of recompression therapy is prudent if concerns for DCS exist.

The differential diagnosis of pulmonary DCS includes AGE. Table 135.3 provides factors that differentiate the two conditions. Although the treatment of both requires recompression therapy, they may be differentiated by the timing of the onset of symptoms. Almost all cases of AGE present within the first 10 minutes of surfacing, whereas DCS presents more typically after 10 minutes: 40% of pulmonary DCS symptoms begin within 1 hour of surfacing, 60% within 3 hours, 80% within 8 hours, and 98% within 24 hours.

**Diagnostic Testing**

Imaging and laboratory studies for ruling in decompression are generally not useful and should not delay definitive recompression therapy. Focused questions concerning the dive profile, including the depth and length of the dive and a careful assessment of when the symptoms first occurred, may provide important diagnostic clues (see Box 135.3). A physician unfamiliar with the specifics of scuba diving may rely on the assessment of members of the dive group to determine whether maximum dive limits were approached. In making the diagnosis of a dive injury, it is helpful to think of the injuries in terms of occurring during descent, while at depth, or during ascent (Fig. 135.9). Because recompression therapy is time sensitive, it is important to concentrate on treatment decisions rather than on securing an absolute diagnosis.

Pulmonary barotrauma can also cause alveolar hemorrhage. Patients may present with hemoptysis coincident with chest pain and dyspnea. Chest radiography may reveal an interstitial infiltrate. Magnetic resonance imaging (MRI), computed tomography (CT), and single-photon emission CT with technetium (Tc-99m)—labeled hexamethyl propyleneamine can identify the bubbles of CNS DCS. However, no imaging studies are sensitive enough to exclude DCS, and normal imaging results should not delay transfer for definitive therapy. DCS can cause right-sided strain on an electrocardiogram and decreased end-tidal carbon dioxide level. Ancillary tests for pulmonary DCS are not only insensitive but also lead to unnecessary treatment delays. Even after ascent from very shallow saturation dives, microbubbles in the venous circulation can be routinely detected by M-mode ultrasonography; however, their presence does not necessarily correlate with symptoms.

**MANAGEMENT**

Patients with stable vital signs and suspected dive injuries should receive 100% oxygen until the clinician can exclude pulmonary barotrauma or decompression illness. First aid with normobaric 100% oxygen can improve outcomes and should be provided until the patient can be definitively treated. Patients with unstable vital signs or in cardiac arrest should be treated according to advanced cardiac life support (ACLS) guidelines. The clinician should take a thorough history, including elements in Box 135.3, and then perform a detailed physical examination.

Diving-related illnesses are diagnosed and treated on the basis of the history and physical examination, and several invaluable resources are available for advice. The Divers Alert Network (DAN), located at Duke University in Durham, North Carolina, is a membership association that provides courses on diving-related emergencies and publishes data on diving accidents and fatalities. DAN provides a 24-hour medical emergency hotline at 1-919-684-9111 (collect calls are accepted) and a nonemergency advisory line Monday through Friday, 8:30 AM to 5 PM Eastern time, at 1-919-684-2948 or 1-800-446-2671 (Box 135.4). In addition, DAN international contacts are in Europe, Brazil, Japan, Asia Pacific, and southern Africa. DAN maintains a website with links

Diving Disorders That Require Recompression Therapy

Decompression sickness type I
Decompression sickness type II
Arterial gas embolism (AGE)
Contaminated air (carbon monoxide poisoning)

Diving Disorders Requiring Recompression Therapy

Diving disorders that require recompression therapy are listed in Box 135.5. Early consultation with a hyperbaric specialist is recommended.

Treatment with 100% oxygen replaces inert gases in the lungs with oxygen. By establishment of a large gradient from the tissues to the alveoli, removal of the inert gases is enhanced and bubble size is reduced. In addition, oxygen administration treats the tissue hypoxia caused by gas bubbles. Normobaric oxygen treatment during preparation for recompression therapy is associated with a need for fewer recompressions.

Dehydration can increase the seriousness of DCS. Hydration decreases bubble formation after decompression. It also decreases the endothelial inflammation and damage associated with hemocoagulation and hemodynamic instability seen in dehydrated DCS patients. Therefore, intravenous fluids should be administered to divers suspected of having nonpulmonary ("choke") DCS. Overly aggressive hydration in divers with pulmonary DCS may worsen pulmonary edema. Similarly, fluid overload should be avoided in patients with cerebral or spinal cord edema. There is no clear consensus that the best fluid is crystalloid (normal saline or lactated Ringer’s solution) or colloid; however, we advise against dextrose in water without electrolytes (eg, dextrose 5% in water [D5W]). Fluids should be given to ensure a urinary output of 0.5 mL/kg per hour.

The intravenous fluid treatment recommendations differ in AGE. Divers with AGE are less likely to be dehydrated than are divers with DCS. This may be because of a shorter period of immersion or because they experience less bubble-induced endothelial damage. Further, CNS injuries in AGE may be worsened by cerebral edema. Therefore, large-volume fluid resuscitation is not recommended in divers with AGE after a short, shallow dive.

The goals of recompression therapy are to reduce the mechanical obstruction of air bubbles, to facilitate the washout of nitrogen by increasing the tissue-blood nitrogen gradient, and to increase oxygen delivery to ischemic tissue. Recompression is the only definitive treatment of DCS and AGE. Treatment of DCS or AGE should not be withheld even if a significant time delay in transfer to a hyperbaric chamber is unavoidable. Although delayed recompression is less effective than immediate recompression in serious cases, the time beyond which recompression offers no benefit is not well documented.

Hyperbaric therapy for AGE should be initiated as soon as possible, because there are cases of significant improvement even in the face of long delays until recompression. Patients with AGE who are recompressed within 5 minutes of surfacing have a mortality rate of 5%, and there is an extremely low risk of morbidity among the survivors. If recompression is delayed by 5 hours or more, the mortality rate increases to 10%, with 50% morbidity. Although spontaneous resolution of symptoms may occur in patients with AGE, all patients should be recompressed. The rationale is that although microbubbles may clear from the cerebral circulation, secondary capillary edema and swelling may result in a delayed recurrence of symptoms. Furthermore, more subtle symptoms may be appreciated only after the resolution of more prominent ones. Finally, minor symptoms may progress, and the relapse rate is high in untreated cases.

Similarly, the prognosis for DCS when it is treated with recompression is generally good but depends on the severity of symptoms at onset and the delay to recompression. A delay to definitive recompression treatment is associated with a worse outcome in cases of severe DCS. Patients can obtain some benefit from recompression, however, even if treatment is initiated more than 24 hours after the dive. Recompression therapy for DCS may be initiated as late as 10 to 14 days after exposure if necessary.

Recompression for DCS and AGE is most often performed in a multiplace chamber with one or more in-chamber attendants. DCS and AGE have also been successfully treated in monoplace chambers. Monoplace chambers are compact, lightweight, and more widely available than multiplace chambers. Unfortunately, because of their design, most cannot be pressurized beyond 3 ata (100 fsw) or deliver air-oxygen mixtures. The most common recompression schedule is United States Navy treatment (or an equivalent procedure); the diver is compressed to 2.8 bar (60 fsw pressure) while breathing 100% oxygen. The time to complete treatment is 4 hours 45 minutes, not including descent time.

Ground transport to a hyperbaric facility is preferred to air transportation, if feasible, because an increase in altitude lowers...
The ambient pressure and allows microbubbles to expand. If air transportation must be used, it is important to maintain cabin pressure at less than 1000 feet. Commercial aircraft are typically pressurized to a cabin altitude of 5000 to 8000 feet in cruise flight (30,000 feet). Many of these aircraft are capable of near-sea level cabin pressures if flying no higher than 15,000 to 20,000 feet. Because helicopters are not pressurized, it is recommended that they maintain an altitude of no more than 500 feet above the departure facility.

In addition to recompression therapy, several adjunctive treatments are proposed in the treatment of DCS and AGE. The treatment or prevention of hypothermia may increase tissue perfusion and off-gassing. The nonsteroidal anti-inflammatory drug (NSAID) tenoxicam (Mobiflex) decreases the number of recompressions required for symptom resolution in DCS but does not change the ultimate outcome. Aspirin therapy (as a platelet aggregation inhibitor) has previously been recommended for DCS and AGE. Because of the lack of studies demonstrating safety and efficacy for DCS or AGE treatment, however, it cannot be recommended. Steroids have previously been advocated clinically for neurologic DCS and AGE. No significant improvements in neurologic sequelae have been demonstrated; however, the elevated blood glucose levels associated with steroid treatment may worsen the outcome of CNS injury.

**Fig. 135.10.** The Divers Alert Network (DAN) On-Site Neurological Assessment for Diver’s History.
Anticoagulants should not be used routinely in the treatment of DCS. The one exception is in divers with lower extremity paralysis caused by neurologic DCS or AGE. Low-molecular-weight heparin (eg, enoxaparin, 30 mg, subcutaneously every 12 hours; dose adjustment should be made for patients with renal impairment) after recompression therapy may be used in patients with inability to walk to prevent venous embolic disease. Intermittent pneumatic compression devices are alternatives. Lidocaine is not effective in DCS but may have neuroprotective effects in patients with AGE and serious neurologic symptoms. It is administered as an intravenous bolus of 1 mg/kg, followed by a drip infusion of 2 to 4 mg/min.

Cardiac dysrhythmias may be refractory to standard treatments until the diver is recompressed. Defibrillation in a hyperbaric environment may be a fire hazard and is not recommended. Seizures may be managed with benzodiazepines; however, mannitol should be avoided. Spinal DCS patients often develop urinary retention requiring bladder catheterization. Of note, endotracheal tube and urinary catheter balloons should be inflated with saline (not air) before recompression therapy is initiated. Nitrous oxide should be avoided because it can increase the size of tissue bubbles by inward diffusion.

Although the head-down position (Trendelenburg) has previously been advocated to prevent migration of intra-arterial bubbles to the brain, it is not effective and may result in worsening cerebral edema and intracranial pressure. Transport of the patient with AGE in a flat supine position is recommended to maximize arterial-venous flow.

There is limited experience with carbon monoxide poisoning from contaminated air supplies in a diving environment. This condition should be treated immediately with normobaric 100% oxygen and may require hyperbaric oxygen therapy. Consultation with a hyperbaric specialist or toxicologist is recommended.

### Diving Disorders Not Requiring Recompression Therapy

Diving disorders that do not require recompression therapy are listed in Box 135.6.

### External Ear Barotrauma

Treatment of external ear barotrauma includes cleaning of the external canal and removal of foreign bodies. Earplugs should not be worn when diving.

### Middle Ear Barotrauma

Prevention of MEBT requires that the diver equalize the pressure in both middle ears. Any diver who cannot clear both ears on the surface should not dive. The diver should not perform a forceful Valsalva maneuver during descent or ascent to clear the ears because of the risk of ABV, round or oval window rupture (descent), or pulmonary barotrauma (ascent). The prophylactic use of pseudoephedrine (60 mg taken 30 minutes before diving) or oxymetazoline nasal spray may reduce the incidence and severity of MEBT. The use of these medications to facilitate diving with symptoms of an upper respiratory infection, however, is not recommended. Antihistamines should be avoided before diving. Sinusitis and upper respiratory infections increase the likelihood of suffering barotitis. Diving should be avoided for 2 weeks after the resolution of an upper respiratory infection.

Treatment of uncomplicated serous otitis from MEBT includes topical nasal vasoconstrictors, such as phenylephrine and oxymetazoline hydrochloride, and repeated Frenzel maneuvers to displace the fluid through the eustachian tube. The Frenzel maneuver is performed by pinching the nose, placing the tongue on the roof of the mouth, as far forward as possible, and gently moving the back of the tongue upward, as when starting to swallow; this is repeated as many times as necessary until equalization occurs. If the physical examination reveals a ruptured tympanic membrane, prophylactic treatment should also include an oral antibiotic. Oral steroids (prednisone) may speed recovery when a seventh nerve palsy is diagnosed in conjunction with a perforated tympanic membrane, although this disorder is typically self-limited. Diving must also be suspended until the tympanic membrane heals to prevent calorigically induced vertigo.

### Internal Ear Barotrauma

A conservative treatment approach to IEBT includes bed rest for 5 to 7 days with the head elevated, avoidance of straining and the Valsalva maneuver, and decongestants to facilitate drainage of the middle ear. Early surgical intervention may benefit patients with total or near-total hearing loss but not isolated high-frequency hearing loss. All patients with IEBT should be referred to an otolaryngologist, because IEBT suggests significant injury to the cochleovestibular system.

### Barosinusitis

Treatment of barosinusitis is typically conservative, including the use of decongestants and, occasionally, antibiotics. If symptoms persist, referral for antrostomy should be considered, particularly to prevent future recurrences. The patient should be advised not to dive until any underlying respiratory infection or acute inflammatory process has resolved.

### Facial Barotrauma

The victim of facial barotrauma may have a dramatic appearance, but the condition is usually benign and requires no specific treatment. The patient should be advised not to resume diving until facial edema resolves.

### Nitrogen Narcosis

Nitrogen narcosis symptoms should resolve on ascending when the partial pressure of nitrogen decreases. Seemingly persistent symptoms should prompt a search for other causes, such as DCS, cerebral AGE, contaminated air, and near-drowning.
Pulmonary Barotrauma

With the exception of AGE, none of the pulmonary barotrauma disorders (pneumothorax, pneumomediastinum, subcutaneous emphysema, and alveolar hemorrhage) requires recompression therapy. Treatment with 100% oxygen may aid in the resolution of the disorders. Although tube thoracostomy may not be required for the treatment of a small pneumothorax, a tube should be placed if the diver is to undergo recompression therapy for concomitant AGE or DCS to prevent a tension pneumothorax. Catheter aspiration of the pneumothorax is an acceptable alternative to tube thoracostomy if the patient will not receive positive-pressure ventilation or recompression therapy.

The evaluation and management of pneumomediastinum include serial chest radiographs to ensure that no coexisting pneumothorax develops. One hundred percent oxygen therapy may hasten the resolution of symptoms. In the rare case of respiratory compromise, tracheal intubation may be required. Most important, the presence of interstitial pulmonary emphysema should alert the physician to the possible coexistence of more severe forms of pulmonary barotrauma. The need for a surgical decompressive treatment of subcutaneous emphysema alone is extremely unlikely. Supportive therapy to correct hypoxia is indicated in the treatment of alveolar hemorrhage.

Alternobaric Vertigo

Careful equalization during a slow ascent can prevent the occurrence of ABV. Oral and intranasal decongestants may be indicated if symptoms persist. Myringotomy is occasionally required.

DISPOSITION

Decompression tables are based on the premise that the diver returns to an ambient pressure of 1 atm on surfacing. However, with ascent in altitude after diving or on diving at altitude, a further reduction in ambient pressure occurs. Commercial airliners may be pressurized to a cabin altitude of 5000 to 8000 feet in cruise flight. Many cases of DCS have a delay in the onset of symptoms in divers who fly after diving even if they are symptom free before departure. Divers who experience DCS symptoms before departure but nevertheless fly are more likely to have type II DCS, less likely to achieve complete relief after recompression, and more likely to have residual symptoms for at least 3 months.

The recommended post-dive preflight surface interval (PFSI) before ascending to higher altitudes (or flying) depends on the diver’s repetitive group designator (residual nitrogen time). The relative risk for development of DCS increases with greater residual nitrogen times and shorter PFSIs (Fig. 135.11). For example, the risk for development of DCS is seven times greater for PFSIs of 12 hours after a dive to 130 fsw than for PFSIs of 24 hours after a dive to 60 fsw. Long PFSIs (up to 48 hours) may be necessary to reduce the risk of DCS after deep, multiday repetitive diving, particularly if the dives required decompression stops (exceeding the no-decompression limits). Some dive computers calculate time-to-flight intervals, which tend to be somewhat shorter than most guidelines based on residual nitrogen timetables. Flying should be delayed for at least 12 hours after diving if less than 2 hours of total dive time was accumulated in the preceding 48 hours. For multiple-day, unlimited diving, flying should be delayed for at least 24 hours. It is prudent to admit all recompressed patients or to advise them to remain within 60 minutes of the hyperbaric facility for 24 hours. Patients recompressed after DCS or AGE should not fly for 72 hours.

United States Navy guidelines recommend that the patient not return to diving for 7 days after recompression for type I DCS and for 4 weeks after type II DCS. The sport diver who experiences DCS type II symptoms or AGE should be discouraged from future diving again.

After treatment for pulmonary barotrauma, divers are evaluated with a spiral volumetric chest CT scan to determine whether there are any preexisting pathologic conditions (eg, bullae) that could put the diver at risk for recurrence before further diving. Chest CT is not used in routine medical screening before participation in scuba diving without a history of pulmonary barotrauma.

Echocardiography to assess for a PFO is often recommended for divers with severe or recurrent neurologic DCS. A substantial amount of venous gas must embolize through the PFO for significant symptoms to occur; that is unlikely to happen in conservative depth-time profiles. A diver with a diagnosed PFO should weigh the risks of continuing to dive and the risks of surgical repair.

Fig. 135.11. The risk of decompression sickness (DCS) relative to flying. fsw, Feet of seawater; msw, meters of seawater. (From Freiberger JJ, et al: The relative risk of decompression sickness during and after air travel following diving. Aviat Space Environ Med 73:983, 2002.)
The majority of dive injuries are diagnosed on the basis of the focused dive history and physical examination alone and are best differentiated into disorders of descent, disorders of depth, and disorders of ascent.

The U.S. Navy Diving Manual and the Divers Alert Network (DAN) are valuable resources for the clinician presented with a diving emergency. DAN provides a 24-hour medical emergency hotline at 1-919-684-9111 (collect calls are accepted) and a nonemergency advisory line Monday through Friday, 8:30 AM to 5 PM Eastern time, at 1-919-684-2948 or 1-800-446-2671 (see Box 135.3).

Treatment with 100% oxygen is the initial therapy for all diving emergencies until the diagnoses can be determined. It has been demonstrated to reduce the morbidity and mortality related to decompression illness and can be helpful in patients with pneumothorax.

Imaging and laboratory studies are not useful for ruling in decompression and should not delay definitive recompression therapy.

With the exception of DCS, AGE, and possibly carbon monoxide poisoning from contaminated air, most dive-related disorders can be treated without recompression therapy. Recompression treatment is recommended for patients with DCS and AGE.

CHAPTER 135: QUESTIONS & ANSWERS

135.1. When is a diver most likely to suffer barotrauma?
A. When the diver also suffers from decompression sickness (DCS)
B. When the diver is at extreme depth
C. When the diver is near the surface
D. When the diver stays at depth for an extended period of time
E. When the diver uses specialized gas mixtures with decreased partial pressure of nitrogen

Answer: C. Barotrauma refers to injuries due to pressure changes. Boyle’s law states that pressure and volume are inversely proportional (P × V = k or P₁V₁ = P₂V₂). As the pressure decreases, the volume of gas increases and can damage gas-filled structures (sinuses, inner/middle ears, lungs, and intestines). The incremental changes in pressure (and therefore volume) are greatest at the surface, so barotrauma most commonly occurs near the surface (either at the beginning or at the end of a dive). Long or deep dives are not required for barotrauma.

135.2. A 55-year-old man presents with the acute onset of left-sided weakness and confusion. Family members report that they are on vacation and had just finished scuba diving when the patient complained of chest pain, became confused, and stopped moving his left arm and leg. This happened 30 minutes ago. The patient has no known medical history and takes no medications. Physical examination reveals a drowsy and confused male who follows commands but does not move his left arm or leg. His blood pressure is 162/98 mm Hg, and his other vital signs are within normal limits. What is the appropriate treatment?
A. Computed tomography (CT) of the brain
B. Endotracheal intubation
C. Intravenous labetalol
D. Intravenous tissue plasminogen activator
E. Recompression in a dive chamber

Answer: E. This patient has suffered an arterial gas embolism (AGE). In AGE, air bubbles gain access to the arterial circulation and can cause mechanical obstruction of the artery. Symptoms can mirror an acute thrombotic or embolic event including myocardial infarction or stroke. Treatment with 100% oxygen should be instituted immediately, but the only definitive treatment is emergent recompression.

135.3. Which of the following individuals should be advised not to dive?
A. A 10-year-old boy with no known medical problems
B. A 19-year-old woman with no medical problems but who just landed from an intercontinental commercial flight
C. A 20-year-old man with well-controlled asthma
D. A 27-year-old woman who is 20 weeks’ pregnant
E. A 70-year-old man with asymptomatic coronary artery disease

Answer: D. Upon surfacing, small nitrogen bubbles form in the circulation of all divers. If proper technique is followed, these bubbles are small and asymptomatic. They form in the venous circulation and are eliminated in the lungs. However, if these bubbles are transmitted into the arterial system, embolization with serious consequences can occur. The fetus has a patent foramen ovale (PFO) and ductus arteriosus, both of which would allow air to bypass this filtering effect of the lungs and proceed into the systemic circulation. Therefore adults with a known PFO should not dive. Asthmatics can dive as long as symptoms are well controlled. There are no definite age recommendations for diving. Flying immediately after diving should be avoided; flying prior to diving is of less concern.

135.4. A 24-year-old woman presents with complaints of severe chest pain and shortness of breath. The symptoms started approximately 1 hour ago while surfacing from a dive. She denies loss of consciousness or other symptoms. Physical examination reveals decreased breath sounds in the right chest and crepitus in her neck; otherwise, it is normal. Vital signs are normal except for a slight tachypnea. A chest radiograph shows a moderate right-sided pneumothorax and a pneumomediastinum. You place a chest tube on her right side. What is the next course of action?
A. Computed tomography (CT) of the brain
B. CT of the chest
C. Observation and supportive care
D. Pericardiocentesis
E. Recompression in a dive chamber

Answer: C. This patient has suffered from pulmonary barotrauma. Although this injury does predispose one to arterial gas embolism (AGE), the diagnosis of AGE is clinical. The treatment for a pneumothorax from pulmonary barotrauma is the same as for a pneumothorax from another cause—that is, aspiration, catheter insertion, or chest tube placement. Management of pneumomediastinum is supportive. Recompression is only necessary for decompression sickness (DCS) or AGE, not for barotrauma.

135.5. A 32-year-old man presents with bilateral lower extremity numbness and weakness. The patient reports several days of scuba diving without incident until his most recent dive, when the symptoms started. Physical examination reveals bilateral lower extremity weakness and decreased sensation to pinprick and light touch. Priapism is also noted. The remainder of the physical
examination and all vital signs are within normal limits. You decide that recompression therapy is indicated, but your emergency department does not have a dive chamber and the nearest chamber is 50 miles away. The patient has been accepted in transfer. What is the most appropriate way to transfer this patient?

A. Air ambulance, lying flat
B. Air ambulance, Trendelenburg position
C. Ground ambulance, lying flat
D. Ground ambulance, Trendelenburg position
E. This patient has not yet been stabilized for transport; he should remain at the current hospital.

Answer: C. This patient is suffering from spinal decompression sickness (DCS II). Recompression therapy is the treatment of choice. Unless an inordinate delay to the recompression chamber would result, anything that further decreases ambient pressure should be avoided (eg, flying). If a patient must be flown, the aircraft should fly at the lowest possible altitude or pressurize the cabin at the highest possible pressure. Traditionally, the Trendelenburg position was advocated because it was believed that it would decrease the incidence of AGE to the brain. This is not the case. In addition, the Trendelenburg position increases cerebral edema and the incidence of coronary artery air embolism. Therefore, the Trendelenburg position should never be used for patients with diving injuries.

135.6. A scuba tank is inadvertently filled with air that contains 100 ppm CO. The diver breathes the compressed air at the surface and has no symptoms. Twenty minutes later at a depth of 100 feet, the diver becomes symptomatic of carbon monoxide poisoning. Why?

A. At depth, blood is preferentially shunted to the brain, so although the concentration of CO does not change, its effects become more prominent.
B. At depth, the body becomes more sensitive to toxins of any sort.
C. At depth, the partial pressure of CO increases and so the concentration in the blood also increases.
D. At depth, the partial pressure of O₂ decreases and so the relative concentration of CO in the blood increases.
E. The depth does not matter; the diver has now been breathing CO for 20 minutes and it has had time to dissolve in the blood.

Answer: C. The partial pressure of all gases increases with depth (pressure). This is Henry’s law. At 100 feet, the total pressure on the body is approximately four times that on the surface. Likewise, the amount of gas dissolved in blood is approximately four times that on the surface. Thus at this depth, it is roughly equivalent to breathing air with a CO concentration of 400 ppm. The diver also has more O₂ dissolved in blood, but this cannot counter the effects of CO because it has a much higher affinity for hemoglobin. Blood flow is not changed at depth. In general, the body is not more susceptible to toxins at depth. Although the amount of time in contact with a poison (eg, CO) does correlate with effects, this is of negligible effect in this case.

135.7. You decide that a 27-year-old patient with an arterial gas embolism (AGE) following scuba diving requires recompression therapy. Which of the following treatments should be initiated before hyperbaric therapy?

A. Administer 40% oxygen.
B. Administer steroids.
C. Ensure that the endotracheal tube and urinary catheter balloons are filled with water, rather than air.
D. Place prophylactic thoracostomy tubes bilaterally.
E. Place the patient in the Trendelenburg position.

Answer: C. Inflate endotracheal tube and urinary catheter balloons with sterile saline. There is no evidence that steroids are effective. The Trendelenburg position increases intracranial pressure and facilitates coronary gas embolization.
Background

Acute high altitude illnesses result from exposure to low oxygen states caused by low atmospheric pressure (hypobaria). Syndromes of the brain and lung are the primary clinical manifestations of high altitude illness. They most typically result from ascent too rapid to allow for adequate acclimatization. Cerebral forms of altitude illness occur as a continuum, from common and benign acute mountain sickness (AMS), to rare, but potentially lethal high-altitude cerebral edema (HACE). High-altitude pulmonary edema (HAPE) is the primary lung syndrome. HAPE is the leading cause of death from altitude illness.

All forms of altitude illness have their origins in acute oxygen insufficiency due to hypobaria. All can be treated with oxygen and descent. Although the percentage of atmospheric oxygen is a constant 20.9%, as elevation increases, atmospheric pressure decreases and with it, oxygen availability. Human physiology is remarkably adaptable when given sufficient time to acclimatize by gradual ascent. Rapid ascent to elevations greater than 8000 feet prevents adequate acclimatization and can lead to debilitating and deadly—and completely avoidable—high altitude illnesses. On the summit of Mt. Everest (8848 m), the partial pressure of inspired oxygen (PiO₂) is only 29% of the sea level value. Although gradual ascents (over weeks) of Mt. Everest without oxygen are remarkably adaptable when given sufficient time to acclimatize by gradual ascent. Rapid ascent to elevations greater than 8000 feet prevents adequate acclimatization and can lead to debilitating and deadly—and completely avoidable—high altitude illnesses. Gradual ascent reduces symptoms and can save lives. Serious altitude illness inevitably follows from unheeded warning symptoms of mild altitude illness. The importance of patient and public education to reduce the morbidity and mortality of serious altitude illness cannot be overstated.

Epidemiology

It is estimated that approximately 40 million individuals worldwide live above 8000 feet. These individuals do not suffer acute altitude illness. Instead, it is the individual (whether for skiing, climbing, travel) who rapidly travels to high altitude who is at greatest risk. In the United States alone, approximately 35 million visitors travel to high-altitude recreation areas every year. Internationally, millions more travel to high mountain ranges of Europe, Asia, Africa, and South America. Each of these transient sojourners is at risk.

The incidence and severity of altitude illness are directly related to elevation and rapidity of ascent. Other variables influencing AMS development including prior acclimatization, individual genetic susceptibility, sleeping elevation, and duration of stay. Rapid ascent to 8000 feet is associated with an approximately 25% incidence of AMS, whereas a rapid ascent (1 or 2 days) to 14,410 feet on Mt. Rainier has rates as high as 67%. Rapidity and mode of ascent also matter; trekkers who fly into the Khumbu region to explore the Mt. Everest area are more likely to develop AMS (47%) than those who walk in from lower elevations (23%).

HACE is much less common than AMS, occurring at well less than 1% of rapid ascents to more than 14,000 feet. Although rare, it carries a grave prognosis if not quickly recognized and treated. The incidence of HAPE varies from 0.01% to 2% in most studies but has reached 15.5% among soldiers flown directly to 14,500 feet without a chance to acclimatize at a lower altitude. Both HAPE and HACE are more common with a longer duration of visit (more than 2 days) and higher sleeping altitude.

Age may be a relative risk factor. Most studies of children suggest that they have the same incidence of AMS as adults. One small study of tourists in Chile evaluated children 4 to 48 months old and found higher AMS scores and lower oxygen saturations compared with those of their parents. Younger individuals (younger than 20 years old) are more likely to have HAPE, although HAPE is extremely rare in children younger than 2 years old. Gender does not affect the incidence of AMS; however, women may have less risk for development of HAPE. No relationship appears to exist between AMS development and the menstrual cycle.

The number of older travelers visiting mountain resorts is increasing. Many of these individuals have underlying health problems, including lung disease, heart disease, and hypertension. Despite these conditions, the risk for AMS development in adults older than 50 years old may be less than in younger age groups. One study found no difference in the incidence or severity of AMS in climbers older than 50 years old compared with a matched cohort of younger climbers. Nevertheless, there are indications that elders may not react well to acute high-altitude exposure. Pulmonary vital capacity decreases almost one-third in elders ascending from sea level to 14,000 feet for 1 week, producing a large decrease in both oxygen saturation and maximal oxygen uptake during exercise.

Definitions

Moderate altitude is between 5000 and 8000 feet of elevation. Rapid ascent to this altitude may result in mild, transient symptoms, but severe altitude illness is uncommon. High altitude is between 8000 and 14,000 feet. Although most people do not experience significant arterial oxygen desaturation until they reach higher altitudes, high-altitude illness is common with rapid ascent above 8000 feet, and individuals with underlying medical problems may be predisposed to development of altitude illness at lower levels. The pathophysiologic effects of high altitude begin when the oxygen saturation of the arterial blood begins to fall below the 90% level. The sigmoidal shape of the oxyhemoglobin dissociation curve prevents a significant fall of arterial oxygen saturation (Sao₂) in most individuals until an altitude of approximately 12,000 feet. At this altitude, the steep portion of the curve is encountered, and marked oxygen desaturation may occur with relatively small increases in altitude (Fig. 136.1). Some predisposed individuals may desaturate to less than 90% at altitudes as low as 8000 feet. Very high altitude is between 14,000 to 18,000 feet. At this elevation, the likelihood of altitude illness is high, and the risk of serious altitude illness (HAPE and HACE) notably increases.
**Acclimatization**

Exposure to acute hypobaric hypoxia results in myriad physiologic responses that act to improve oxygenation. **Acclimatization** is both immediate (within minutes the carotid bodies sense hypoxemia) and continuous over months (hemoglobin increases may continue over more than 6 weeks). It involves multiple systems from protein synthesis to respiratory, cardiovascular, renal, and hematologic responses.

Acclimatization begins as the oxygen saturation of arterial blood falls below sea-level values. The altitude at which this occurs depends on the rate of ascent, the duration of exposure, and the individual’s physiology. People with preexisting conditions that limit cellular oxygen delivery and pulmonary reserves may have a decreased altitude tolerance. Most healthy, unacclimatized visitors to high altitude will not desaturate significantly (to less than 90%) until they reach elevations higher than 8000 feet.

The risk of high-altitude illness depends on an individual’s inherent ability to acclimatize. Some people acclimatize easily without having any clinical symptoms. Others may transiently have AMS during acclimatization, and a few have marked reactions to altitude exposure, developing severe altitude illness. This variability involves many genetic and epigenetic factors that influence acclimatization. Previous successful acclimatization may be predictive of future responses for adults in similar conditions, but this may not be the case for children.

One of the most fundamental physiologic changes that occur during acclimatization is an increase in minute ventilation. Within minutes of exposure to high altitude, the peripheral chemoreceptors in the carotid bodies sense the decrease in the partial pressure of oxygen in alveoli (\(P_{A\text{O}_2}\)) and signal the respiratory control center in the medulla to increase ventilation. Increased minute ventilation causes a decrease in the partial pressure of carbon dioxide in alveoli (\(P_{A\text{CO}_2}\)). As described by the alveolar gas equation, for any given inspired oxygen tension, the level of ventilation determines alveolar oxygen: as the \(P_{A\text{CO}_2}\) decreases, \(P_{A\text{O}_2}\) correspondingly increases (Box 136.1). This increased ventilation in response to hypoxic challenge is known as the **hypoxic ventilatory response (HVR)**. The magnitude of the HVR varies among individuals and may be genetically predetermined. HVR may also be inhibited or stimulated by numerous factors, including ethanol, sleep medications, caffeine, cocoa, prochlorperazine, and progesterone.

As minute ventilation increases, carbon dioxide exhalation increases; and within minutes, a resulting respiratory alkalosis acts on the central respiratory center to limit further increases in ventilation. To compensate for this respiratory alkalosis, the kidneys begin to excrete bicarbonate. Acetazolamide enhances this excretion. Gradual, progressive renal excretion of bicarbonate allows ventilation to rise slowly, reaching a maximum after 6 to 8 days at a given altitude. An individual’s HVR is related to their ability to acclimatize. A low HVR and relative hypoventilation are implicated in the pathogenesis of both AMS and HAPE. For the majority of people with intermediate HVR’s, however, ventilatory response to hypoxia is not predictive of future responses for adults in similar conditions, but this may not be the case for children.

### Environmental Considerations

Barometric pressure decreases logarithmically as the altitude rises. The pernicious effects of altitude are due to hypobaric hypoxia; as atmospheric pressure decreases the partial pressure of oxygen (\(P_{O_2}\)) decreases. The earth is slightly flat at the poles and bulging at the equator. The atmospheric envelope that surrounds the earth decreases with altitude. In October 2008, Mount Everest II: oxygen transport during exercise at extreme simulated altitude. J Appl Physiol 64:1309, 1988.

**Extreme altitude** is above 18,000 feet. Although climbers using careful acclimatization schedules can transiently tolerate this height, complete acclimatization generally is not possible and long visits above this level result in progressive deterioration. Given limitations in physiologic reserves, climbers who become incapacitated at this elevation typically are dependent on others to survive.

`Fig. 136.1. Oxygen-hemoglobin dissociation curve. Approximate oxygen saturations are marked for several altitudes. \(P_{O_2}\), Partial pressure of oxygen. (Data for 15,000 to 29,029 feet from Sutton JR, et al: Operation Everest II: oxygen transport during exercise at extreme simulated altitude. J Appl Physiol 64:1309, 1988.)`

- **\(P_{I\text{O}_2}\)**: Partial pressure of oxygen in inspired air
- **\(P_{A\text{CO}_2}\)**: Partial pressure of carbon dioxide in alveolus
- **\(R\)**: Respiratory quotient

---

---
The hematopoietic response to high-altitude acclimatization includes an increase in both hemoglobin and the number of red blood cells. As a result of fluid shifts into the extravascular space, mean corpuscular hemoglobin concentration increases up to 15% after rapid ascent to high altitude. Long-term acclimatization leads to an increase in plasma volume and total blood volume. Erythropoietin is secreted in response to hypoxemia within hours of ascent, which in turn stimulates the production of red blood cells, leading to new circulatory red blood cells in 4 or 5 days. During the next 2 months, red blood cell mass increases in proportion to the degree of hypoxemia.

Hypoxemia also results in an increase in 2,3-diphosphoglycerate, causing a rightward shift of the oxyhemoglobin dissociation curve, which favors a release of oxygen from the blood to the tissues. This is counteracted by the leftward shift of the oxyhemoglobin dissociation curve caused by the respiratory alkalosis from hyperventilation. The result is a net null change in the oxyhemoglobin curve and an increase in oxygen-hemoglobin binding in the lung, which raises \( \text{SaO}_2 \). Some individuals with mutant hemoglobin and high oxygen-hemoglobin affinity are found to acclimatize more efficiently than their normal counterparts at moderate altitudes.

**Pathophysiology**

Although acute hypoxia elicits a broad array of physiologic responses, the clinical syndromes of high-altitude illness predominantly affect the brain and lungs. Hypobaric hypoxia’s effects on central nervous system homeostasis give rise to AMS and HACE. AMS is the common, benign form that unheeded, can develop into rare, but potentially lethal HACE. HAPE results from overly exuberant increases in pulmonary arterial pressures that lead to stress failures of the delicate pulmonary capillary beds.

Although discrete physiologic responses occur within minutes of exposure to acute hypoxia, the clinical syndromes of high altitude typically require hours to days to manifest themselves. AMS can develop within 4 to 8 hours of acute exposure to hypobaric hypoxia. HACE and HAPE typically occur 2 to 4 days after exposure to high altitude. Because hypobaric hypoxemia occurs within minutes of arrival, it cannot be the direct cause of high-altitude illness. Instead, it appears to be the initiating factor for a complex pathologic process that leads to the development of the various clinical syndromes. The proposed mechanisms for the development of AMS, HAPE, and HACE are represented schematically in Figure 136.2.

**Fig. 136.2.** Proposed mechanisms for the development of acute mountain sickness (AMS), high-altitude pulmonary edema (HAPE), and high-altitude cerebral edema (HACE). CNS, Central nervous system; ICP, intracranial pressure.
HVR is the first response to insufficient oxygen, leading to increased minute ventilation. A robust HVR tends to be protective by encouraging compensatory ventilation. A limited HVR leads to relative hypoventilation and inadequate response to the hypoxemia of high altitude.

Centrally mediated periodic breathing associated with high-altitude exposure may result in periods of apnea during sleep, causing severe arterial oxygen desaturation, which further exacerbates hypoxemia. Significant hypoxemia initiates multiple systemic responses that involve the circulatory, pulmonary, endocrine, and central nervous systems.

Hypoxemia alters fluid homeostasis, resulting in a generalized fluid retention followed by the shift of fluid into the intracellular spaces. This is manifested by peripheral edema, decreased urinary output, decreased central vascular volume, and increased body weight in patients with AMS. Several different mechanisms may account for these fluid shifts, including arginine vasopressin levels and sympathetic stimulation that may be centrally mediated. Arginine vasopressin levels are elevated in some cases of AMS and HAPE and decreased in others. Aldosterone, plasma renin, and atrial natriuretic levels are higher in people with AMS.

HAPE results from hypoxia-induced acute pulmonary hypertension leading to stress failure of pulmonary capillaries with consequent alveolar and interstitial edema. Although exercise and cold stress at altitude may increase hypoxemia and exacerbate pulmonary hypertension, the hypoxic pulmonary vasoconstrictive response (HPVR) acts as the primary mediator. HPVR results in pulmonary arterial smooth muscle contraction within the typically low-pressure pulmonary arterial system, with consequent increases in pulmonary arterial pressures within minutes. The HPVR can vary widely between individuals and can even vary widely in different regions of the lungs of the same individual. This unevenness of pulmonary vasoconstriction within an individual’s lung is thought to contribute to the pathophysiology of HAPE. In patients with HAPE, exaggerated pulmonary arterial pressures (mean pressure 36 to 51 mm Hg) occur. Uneven vasoconstriction forces the pulmonary hypertension to be transmitted to delicate capillary vessels in an uneven fashion, leading to the failure of capillary endothelium with resultant alveolar and interstitial edema. This uneven edema explains the patchy nature of the infiltrate seen on a chest radiograph with HAPE. It should be noted that although elevated pulmonary arterial pressure is the sine qua non of HAPE, even marked acute pulmonary hypertension is not alone sufficient to cause HAPE.

The mechanism for the uneven vasoconstriction in HAPE may be due to decreased nitric oxide bioavailability at the pulmonary tissue level. That HAPE has its origins in acute pulmonary hypertension and resultant over-perfusion is supported by studies revealing that pharmacologic agents that limit excessive rises in pulmonary artery pressure prevent HAPE and findings that patients with congenital unilateral absence of a pulmonary artery (and so the entire cardiac output is delivered to one lung) have increased HAPE susceptibility.

Once mechanical injury and pulmonary edema occur, other factors come into play. Acute inflammatory mediators appear and likely contribute to worsening lung function. As alveolar fluid accumulates, impairment in a patient’s transepithelial sodium transport may decrease their ability to clear alveolar fluid and so worsen HAPE. Sodium channel-mediated alveolar fluid clearance is upregulated by inhaled beta-adrenergic agonists, which have been proven to decrease risk of HAPE.

Preexisting inflammation may also be a risk factor for HAPE. Particularly in children, preexisting respiratory infection during ascent to high altitude increases susceptibility to HAPE. Inflammation may “sensitize” the pulmonary endothelium to mechanical injury and increase susceptibility to alveolar fluid accumulation and HAPE during ascent.

The definitive etiology of the cerebral forms of altitude illness remains unclear. Evidence suggests that clinical manifestations of AMS and HACE result from the combined effects of altered cerebral hemodynamics and inflammatory mediators. Within minutes of exposure to hypoxia, cerebral vasodilation occurs with increased arterial blood flow and volume. Hypocapnia (secondary to increased ventilation) creates a countervailing cerebral vasoconstriction. The overall effect is one of increased cerebral blood flow. Given the rigid confines of the skull, increases in intracranial blood volume require compensatory changes in the brain and cerebral spinal fluid or intracranial pressures will inevitably increase. CNS hypoxemia leads to impaired vascular auto-regulation, causing increased pressures within the brain’s capillary beds. In addition, systemic hypertension from strenuous exercise at high altitude may overwhelm the brain vasculature, resulting in transcapillary leakage and vasogenic edema. In susceptible individuals, these hemodynamic changes are likely to contribute to clinical manifestations of AMS and HACE.

Additional circumstances, however, may be necessary for the development of vasogenic edema and clinical symptoms. Inflammatory mediators may contribute to edema formation. Vascular endothelial growth factor, the inducible form of nitric oxide synthase, reactive cytokines, and free radical formation may mediate brain endothelial permeability. The roles that these play in the pathophysiologic process of altitude illness remain unclear.

The role of vasogenic edema in AMS is of unclear significance. Magnetic resonance imaging (MRI) of subjects acutely exposed to hypoxia reveal similar signal changes in both subjects with and without clinical AMS. In patients with HACE, MRI studies reveal characteristic white matter changes consistent with vasogenic edema that correlate with symptoms. Although still an area of active research, AMS and HACE pathophysiology is likely due to disturbances in the blood-brain barrier through a combination of mechanical factors and biochemical mediation of permeability.

In severe AMS, MRI studies have revealed cytotoxic edema to present. Rather than being the primary mechanism of severe AMS/HACE, this cytotoxic edema is likely secondary to increased cell ischemia resulting from initial hemodynamic changes, vasogenic edema, biochemical mediators, and increased ratios of brain volume to intracranial space.

Increasing data highlight the independent role of hypobaria in the development of AMS and on physiologic responses, including heart rate. In experiments where subjects are exposed to identical levels of alveolar oxygen deprivation, subjects exposed to normobaric hypoxia (by decreasing fraction of inspired oxygen [FiO₂]) alone have much lower AMS incidence than subjects exposed to a hypobaric hypoxia. The exact pathophysiologic role of hypobaria in altitude illness remains unclear.

Although the “tight fit” hypothesis was proposed more than three decades ago to explain AMS development and its inherent individual susceptibility, the role of increased intracranial hypertension in AMS remains of area of active research. This theory suggests that susceptibility to AMS and HACE increases as a subject’s ability to accommodate hypoxia-related increased intracranial blood volume and cerebral edema decreases. As brain volume increases from increased cerebral blood volume, the volume-buffering capacity of the central nervous system may prevent an immediate rise of intracranial pressure. As brain volume increases, the intracranial cerebrospinal fluid (CSF) is displaced through the foramen magnum into the spinal canal. Increased absorption of CSF by the arachnoid villi and decreased CSF production also occur. Individuals with less intracranial and intraspinal CSF buffering capacity have less compliance, and so larger increases in intracranial pressure, and become more symptomatic (ie, develop AMS) from mild brain swelling. The tight fit hypothesis is supported by lumbar puncture, MRI, and computed tomography (CT) studies. More recently, optic nerve sheath
ultrasonography has emerged as an early, noninvasive diagnostic tool to assess intracranial pressure. Increasing intracranial pressure correlates directly with optic nerve sheath diameter (ONSD). Studies have demonstrated that elevated intracranial pressure is associated with AMS and HACE.

**ACUTE MOUNTAIN SICKNESS**

**Clinical Features**

AMS is a clinical diagnosis. As defined by the Lake Louise Criteria, the diagnosis of AMS requires a patient to have recently ascending to an elevation of 8000 feet, with report a headache plus at least one of the following symptoms: gastrointestinal upset (anorexia, nausea, or vomiting), general weakness or fatigue, dizziness or lightheadedness, or difficulty in sleeping (Box 136.2). The headache may vary from mild to severe, is generally bitemporal and throbbing in nature, and is worse during the night and on awakening or on suddenly becoming upright. Anorexia and nausea, with or without vomiting, are common, and the other symptoms described can range in severity from mild to incapacitating. The disturbance of sleep caused by periodic breathing is common in all visitors to high altitudes but may be exacerbated in the setting of AMS. The symptoms of AMS develop within a few hours after arrival at high altitude and generally reach maximum severity between 24 and 48 hours, followed by a gradual resolution. Most individuals become symptom free by the third or fourth day. Patients with continued symptoms should not ascend until symptoms abate, and descent and alternative diagnoses should also be considered.

Given its subjective nature, AMS is difficult to definitively diagnose in infants and pre-verbal children. AMS may be manifested by increased fussiness, decreased playfulness, decreased appetite, and sleep disturbance. Although AMS, or a change in environment, sleeping accommodation, or eating habits may result in a fussy, unhappy child, the differential diagnosis for these nonspecific findings must remain broad. If occult bacteremia or another serious illness is suspected in a young child, prudence requires descent to lower altitude and an appropriate diagnostic and treatment regimen.

**Differential Diagnosis**

AMS is a clinical diagnosis without objective diagnostic physical findings. A prudent physician maintains a broad differential diagnosis when treating these nonspecific symptoms (Box 136.3).

**Box 136.2**

**Acute Mountain Sickness**

Incidence: 12% to 67%, varies widely with elevation, rate of ascent and individual susceptibility; rare below 8000 feet, most common with rapid ascent to altitudes above 10,000 feet.

Symptoms and signs: Headache, anorexia, nausea, fatigue, dizziness, difficulty sleeping.

Treatment: Mild cases are usually self-limited and do not require treatment; discontinue ascent, rest. For moderate cases, administer acetazolamide; ibuprofen, aspirin, or acetaminophen for headache; prochlorperazine for nausea; supplemental oxygen if available; descend if persistent or severe; add dexamethasone in severe cases.

Prevention: Gradual ascent to allow acclimatization; high-carbohydrate diet, avoidance of ethanol or smoking; acetazolamide if ascent is rapid or known history of recurrent acute mountain sickness (AMS).

**Box 136.3**

**Acute Mountain Sickness Differential Diagnosis**

- Tension headache
- Viral syndrome
- Alcohol intoxication/toxidrome
- Carbon monoxide (CO) poisoning
- Dehydration
- Caffeine withdrawal
- Migraine headache
- Infectious ( meningitis, encephalitis/viral syndrome)
- Intracranial hemorrhage or mass
- Central nervous system aneurysm
- Venous sinus thrombosis
- Abdominal process (eg, gastroenteritis)
- Acute angle closure glaucoma/ocular process

Less common, but lethal etiologies of headache, nausea, and fatigue must be considered before the benign diagnosis of AMS is made. Any evidence of ataxia or altered mentation gives evidence of HACE and mandates immediate descent. Benign focal neurologic findings and transient global amnesia have been described at altitude but should be assumed to be malignant in etiology until proven otherwise. Acute carbon monoxide (CO) poisoning is more likely than in other environments. Although dyspnea on exertion is universal and expected at high altitudes, dyspnea at rest gives evidence of HAPE. A careful examination for pulmonary edema is indicated.

**Diagnostic Testing**

Serial measurement of ONSD using ultrason has demonstrated that subjects with symptoms and signs of worsening AMS or HACE have enlarged ONSDs on serial measurements, which may prove a useful adjunct in the diagnosis and monitoring of AMS and HACE (Fig. 136.3).

**Management**

Patients with AMS should not ascend to a higher sleeping altitude until symptoms resolve to allow acclimatization to occur. Continued ascent exacerbates the underlying pathologic processes and may lead to severe AMS or lethal HACE. If patients develop neurologic abnormalities (eg, ataxia or altered mentation) or evidence of severe pulmonary edema, immediate descent is indicated.

Mild AMS may be treated by symptom management and cessation of ascent until acclimatization occurs. This may take 1 to 4 days. AMS that becomes worse or does not respond to maintenance of altitude, rest, and pharmacologic intervention necessitates descent. A descent of as little as 500 feet may be sufficient. Descent of 1500 to 3000 feet effectively reverses high-altitude illness in most cases. Descent should be continued until improvement is seen, and efforts to minimize exertion should be instituted during the descent.

**Oxygen Therapy**

All forms of altitude illness, including AMS, are effectively treated with supplemental oxygen. In mild AMS, supplemental oxygen is a luxury. For severe forms of altitude illness, oxygen can be lifesaving. In resort settings, oxygen can often be rented directly from the hotel or condominium. For AMS, low flow oxygen (1 to 2 L/min), including small amounts during sleep, is often sufficient. In
Analgesics and Antiemetics

Symptomatic treatment of headache and nausea can be beneficial during the course of mild AMS. Aspirin, ibuprofen, and acetaminophen are useful for the treatment of high-altitude headache. Narcotic analgesics should be avoided because of depression of the hypoventilation response (HVR) and respiratory drive during sleep. For nausea and vomiting, prochlorperazine unlike other antiemetics, stimulates the HVR.

Acetazolamide

Periodic breathing causes insomnia, which is best treated with the respiratory stimulant acetazolamide. Doses of acetazolamide as low as 62.5 mg to 125 mg bid may prevent periodic breathing and eradicate insomnia. Most benzodiazepines and other sedative-hypnotics should be avoided because of their tendency to decrease ventilation during sleep. Even individuals who have previously used diazepam at lower altitudes without difficulty describe unusual reactions, including agitation, hallucinations, and disorientation when this agent is used at high altitude. Studies suggest that low doses of benzodiazepines in combination with acetazolamide are safe at high altitude. A study comparing a single 7.5 mg dose of temazepam to 125 mg of acetazolamide found temazepam significantly improved sleep quality and reduced episodes of nocturia, without increasing oxygen desaturation. Nonbenzodiazepine sleep agents (such as, zolpidem and zaleplon) do not depress ventilation and may prove useful in AMS-related insomnia.

Acetazolamide accelerates acclimatization and, if given early in the development of AMS, may rapidly resolve symptoms. Although the optimal dose has not yet been definitively established, a dose of 250 mg of acetazolamide at the onset of symptoms and repeated twice daily is effective therapy for AMS. The treatment of AMS in children is not formally studied, but anecdotal experience supports the use of acetazolamide in children. The dose for children is 2.5 mg/kg/dose or 125 mg given twice daily to a maximum of 250 mg.

Acetazolamide has myriad beneficial effects. By acting as a carbonic anhydrase inhibitor, it enhances renal bicarbonate diuresis and so improves renal correction of the ventilation-related respiratory alkalosis encouraging increased ventilation and arterial oxygenation. It decreases nocturnal period breathing and so improves sleep. It acts as a diuretic and so attenuates fluid retention common in patients with AMS. It lowers CSF volume and pressure, which may play an additional role in its therapeutic effect. In addition, it has positive effects beyond its role as a carbonic anhydrase inhibitor, with beneficial chemoreceptor effects on ventilatory drive, alterations of cerebral blood flow, relaxation of smooth muscles, and upregulation of fluid resorption in the lungs.

The most common adverse reactions to acetazolamide are paresthesias and polyuria. Less common reactions include nausea, diarrhea, drowsiness, tinnitus, and transient myopia. Carbonic anhydrase inhibition at the tongue causes dysgeusia, altering the flavor of carbonated beverages, including beer. Acetazolamide is a non-antibiotic sulfa compound that carries a low risk of cross-reactivity for individuals with an allergy to sulfa antibiotics. Patients with known sulfonamide allergy may consider administration of a trial dose of acetazolamide in a controlled environment before ascent. Acetazolamide is contraindicated in patients with a history of anaphylaxis or severe skin reactions to any sulfa-containing medication, and it should be avoided in breast-feeding mothers and pregnant women.

Dexamethasone

Dexamethasone is an effective alternative treatment of moderate to severe AMS. An initial dose of 8 mg, followed by 4 mg every 6 hours is recommended. Anecdotal reports indicate doses as low as 2 mg may be sufficient. As a treatment option, concurrent use with acetazolamide is advocated by some to promote acclimatization. Dexamethasone known to have anti-inflammatory properties, possibly to reduce cerebral blood flow, and to block the action of vascular endothelial growth factor. Reduction of AMS symptoms with the use of dexamethasone may be the result of these or its euphoric effects. Prophylactic use of dexamethasone should generally be reserved for use in individuals forced to rapid ascent (eg, professional mountain search and rescue operations). Although dexamethasone effectively relieves the symptoms of AMS, unlike acetazolamide it does not enhance acclimatization. If used as a prophylactic agent to allow ascent beyond physiologic acclimatization, acute cessation can result in rapid onset of severe
altitude illness. For treatment, use should be limited to patients with acetazolamide intolerance or more advanced cases of AMS, especially to help facilitate descent. Common side effects of dexamethasone include gastrointestinal irritation, gastritis, esophagitis, altered mood, and gastroesophageal reflux disease (GERD). Dexamethasone should not be used for more than 3 days in this indication.

Disposition

Individuals with AMS may resume their ascent after symptoms resolve. Re-ascent with acetazolamide use in these individuals is recommended. Further ascent should be halted if symptoms recur.

Prevention

Most of the symptoms of mild AMS are benign and well tolerated. These symptoms, however, can be unpleasant and debilitating to the point that travel, business, or vacation plans should be interrupted. Up to 50% of individuals with AMS report a decrease in activity.

The best method of prevention is a gradual or staged ascent that allows adequate time for acclimatization; however, the time constraints of many vacationers and inexperienced guides often make such an ascent unrealistic. The altitude of sleep during any individual ascent is critical. Ideally, the first night should not be spent at an altitude higher than 9200 feet, with a subsequent increase (to a new sleeping altitude) of not more than 1600 feet each night. One extra night of acclimatization (at the same sleeping altitude) should be added for every 3000 to 5000 feet of altitude gain above 10,000 feet. Excursions to higher altitudes during the day with a return to a lower sleeping altitude (“climb high, sleep low”) aid in acclimatization.

Altitude pre-exposure regimens in artificially hypoxic environments have been evaluated to facilitate acclimatization. Pre-exposure regimens lasting less than 8 to 12 hours appear to offer limited protection from subsequent altitude exposure.16,17

Mild to moderate exercise likely aids acclimatization; however, overexertion can contribute to the development of AMS. Maintaining adequate hydration—targeting relatively clear (dilute) urine and normal urine output—is also recommended. No data support recommendations for hyperhydration that is often promoted in the lay literature. In fact, consumption of excessive amounts of free water may lead to hyponatremia and possibly complicate altitude illness. Balanced electrolyte solutions are recommended (premixed or prepared with purified water).

The goal elevation, rate of ascent, and prior history of altitude illness should be considered in the assessment of the risk for development of altitude illness and the choice of prevention strategies (eTable 136.1). Individuals in low-risk situations should not need medications for prophylaxis. Ascent should be gradual to prevent illness. In some cases, such as arrival at a high-altitude airport or the immediate dispatch of rescue personnel to high altitude, a slow or staged ascent is impossible. Mountain climbers commonly ascend at rates that are higher than recommended, and some individuals continue to suffer AMS symptoms despite gradual ascent. Individuals who have a known susceptibility to the development of AMS and those for whom slow ascent is impractical fall into the moderate- and high-risk categories and should consider prophylactic medication in addition to gradual ascent.17

Numerous studies demonstrate the effectiveness of acetazolamide in prevention of AMS in adults.18 Lower doses provide prophylaxis similar to that of higher dosages with fewer adverse reactions. Many studies demonstrate that 250 mg twice daily starting 24 hours before ascent and continuing for the first 2 days at high altitude is effective. For avoidance of side effects, a dose of 125 mg given twice daily is effective. 2 Although it is unstudied, the recommended dosage of acetazolamide for AMS prophylaxis for children is 2.5 mg/kg/dose up to 125 mg total given twice daily, and this weight-based approach may reduce side effects in smaller adults. Ibuprofen compared with acetazolamide is equally efficacious in preventing headache.

Dexamethasone also prevents AMS. The lowest effective dosage is 2 mg every 6 hours or 4 mg every 12 hours. Some patients experience the rapid onset of AMS after dexamethasone is discontinued. Dexamethasone does not facilitate acclimatization but rather reduces nausea and enhances mood. In most cases, dexamethasone use should be reserved for treatment of AMS rather than for prophylaxis. Military or rescue personnel rapidly ascending to high altitude and individuals with acetazolamide intolerance are candidates for prophylaxis with dexamethasone. The combination of acetazolamide and dexamethasone may be more effective than either drug alone.

Compelling data do not support the use of Ginkgo biloba for preventive therapy of AMS.

Oxygen is an effective prophylactic modality for rescue personnel. Adequate supplies should be available to ensure the safety of all team members for the entire duration of the rescue. Air drops of oxygen can be lifesaving when weather or terrain prevents the immediate arrival of rescue personnel.

HIGH-ALTITUDE PULMONARY EDEMA

Principles

HAPE is the most common fatal manifestation of severe high-altitude illness (Box 136.4). Although HAPE is uncommon below 10,000 feet, it can occur and even be fatal at altitudes below 8,000 feet. Episodes occurring between 8000 and 10,000 feet are usually related to heavy exercise; but at higher altitudes, pulmonary edema can also occur at rest or with light activity.

Some individuals are susceptible and experience HAPE with each ascent to altitude. Rarely, the congenital absence of a pulmonary artery exaggerates the pulmonary vascular response to hypoxia, resulting in recurrent HAPE at elevations lower than expected. Many patients, however, have a single episode of HAPE and subsequently are able to return to high altitude without a recurrence. Less commonly, those with multiple previously uneventful high-altitude exposures may still develop HAPE.

### BOX 136.4

**High-Altitude Pulmonary Edema**

**Incidence:** 0.01% to 15%, varies with elevation and rate of ascent; rare below 8000 feet and more common above 14,500 feet; typically occurs 2 to 4 days after arrival at high altitude.

**Symptoms and signs:** Dyspnea at rest, cough, anorexia, cyanosis, rales, tachypnea, tachycardia.

**Treatment:** Patients with mild cases may recover with bed rest. Moderate cases can be treated with bed rest and supplemental oxygen if clinical monitoring is available. Severe cases require oxygen and descent; use hyperbaric therapy if available; if oxygen or descent is unavailable, then nifedipine 30 mg slow-release every 12 hours; consider acetazolamide (125–250 mg every 12 hours) and tadalafil 10 mg every 12 hours (unstudied).

**Prevention:** Gradual ascent and recognition of early AMS symptoms so that ascent is stopped before HAPE develops; with previous HAPE history, use nifedipine 30 mg slow-release every 12 hours during ascent, then continue for 3 days (monitor for hypotension).

AMS, Acute mountain sickness; HAPE, high-altitude pulmonary edema.
### TABLE 136.1

**Risk Categories for Acute Mountain Sickness***

<table>
<thead>
<tr>
<th>RISK CATEGORY</th>
<th>DESCRIPTION</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Low</strong></td>
<td>Individuals with no prior history of altitude illness and ascending to ≤9200 feet. Individuals taking ≥2 days to arrive at 8200 to 9800 feet with subsequent increases in sleeping elevation &lt;1600 feet per day.</td>
</tr>
<tr>
<td><strong>Moderate</strong></td>
<td>Individuals with prior history of AMS and ascending to 8200 to 9200 feet in 1 day. No history of AMS and ascending to &gt;9200 feet in 1 day. All individuals ascending &gt;1600 feet per day (increase in sleeping elevation) at altitudes above 9800 feet.</td>
</tr>
<tr>
<td><strong>High</strong></td>
<td>History of AMS and ascending to ≥9200 feet in 1 day. All individuals with a prior history of HAPE or HACE. All individuals ascending to &gt;11,500 feet in 1 day. All individuals ascending &gt;1600 feet per day (increase in sleeping elevation) above &gt;11,500 feet. Very rapid ascents (eg, Mt. Kilimanjaro).</td>
</tr>
</tbody>
</table>

*Altitudes listed in the table refer to the altitude at which the person sleeps. Ascent is assumed to start from elevations <4000 feet. The risk categories described pertain to unacclimatized individuals. AMS, Acute mountain sickness; HACE, high-altitude cerebral edema; HAPE, high-altitude pulmonary edema. Modified from Luks AM, et al: Wilderness Medical Society consensus guidelines for the prevention and treatment of acute altitude illness. Wilderness Environ Med 21:146-155, 2010.*
Individuals who have been residents at high-altitude locations for extended periods may have pulmonary edema develop on re-ascent from a trip to low altitude. This phenomenon has been termed reentry HAPE. The incidence of reentry HAPE is not established; however, there seems to be an increased risk for children and young adults. This apparent increased susceptibility among children for development of HAPE is probably the result of developmental changes in pulmonary vascular reactivity and tone.

**Clinical Features**

The initial symptoms of HAPE usually begin insidiously 2 to 4 days after arrival at high altitude. Most cases occur during the second night, but HAPE may develop rapidly, with early symptoms apparent after just a few hours at high altitude. Marked dyspnea on exertion, fatigue with minimal-to-moderate effort, prolonged recovery time, and dry cough are early manifestations of the disease. The symptoms of AMS usually occur concurrently with the development of HAPE.

As the HAPE patient deteriorates, usually through the night, the dyspnea intensifies with effort and is unrelieved by rest. Dyspnea at rest should be recognized as a red flag warning. The cough may become productive of copious amounts of clear, watery sputum. Hemoptysis may be seen in severe cases. As the condition intensifies, cerebral edema or simply severe hypoxemia causes central nervous system dysfunction, such as ataxia and altered mentation. Coma may follow and precede death in a few hours if immediate oxygen therapy and descent are not instituted.

The physical examination reveals a few rales in patients with mild HAPE, usually found in the region of the right middle lobe, progressing to unilateral or bilateral rales and then to diffuse bilateral rales and also rhonchi and gurgles audible without the stethoscope. Neck veins are not distended. Cyanosis of the nail beds alone may progress to severe central cyanosis. Tachypnea and tachycardia become more pronounced as severity increases. Elevated temperatures are common, and a concurrent respiratory tract infection is occasionally seen, especially in children.

**Differential Diagnosis**

It is prudent to maintain a wide differential diagnosis in assessing patients with acute dyspnea at high altitude (Box 136.5). Although HAPE occurs at high altitude, so do acute coronary syndrome, pulmonary embolism (PE), congestive heart failure (CHF), and pneumonia.

**BOX 136.5**

**High-Altitude Pulmonary Edema**

**Differential Diagnosis**

- Carbon monoxide (CO) poisoning
- Pneumonia
- Pneumothorax
- Pleural effusion
- Pulmonary embolism (PE)
- Acute coronary syndrome
- Acute congestive heart failure (CHF)
- Acute exacerbation of preexisting pulmonary hypertension
- Acute flare of chronic obstructive pulmonary disease (COPD)
- Acute asthma flare
- Acute exacerbations of valvular disease (insufficiency and stenosis)

Pneumonia can be misdiagnosed in the setting of HAPE because the symptoms and signs of pneumonia are similar to those of HAPE. The incidence of pneumonia and the common organisms responsible for pneumonia at high altitude are unknown, but visitors to high altitudes may be predisposed to acquire bacterial infections because of impaired T-lymphocyte function. Patients who present with symptoms compatible with pneumonia at high altitude should be treated for HAPE. If any doubt exists about the diagnosis of HAPE versus pneumonia, empirical antibiotic therapy should be initiated. Because of decreased respiratory reserves and mild immunosuppression coincident with high-altitude exposure, the treatment of any serious pulmonary infection at high altitude requires oxygen, descent, and antibiotics.

High-altitude bronchitis and pharyngitis are common problems among climbers. They may result from the increased ventilation of cold, dry air across the upper airway mucosa, causing mucosal inflammation. Copious sputum production is sometimes seen, and antibiotic therapy is rarely helpful. Coughing spasms may be severe and require treatment with antitussives. Other therapeutic measures include hydration, lozenges, and steam inhalation.

Death from PE at high altitude is described. Given frequent travel involving long plane flights prior to many vacations at high altitude, patients may often have increased pre-test likelihoods of deep vein thrombus (DVT) and PE. Additional predisposing factors for DVT may include acute hyperviscosity due to increased hematocrit, dehydration, and forced stasis due to weather. The symptoms and signs of PE can mimic those of HAPE; however, embolic disease tends to have a more rapid onset, and pleuritic chest pain is a more prominent feature.

**Diagnostic Testing**

**Ultrasoundography**

Ultrasound machines are portable, require limited training for effective use in this setting, and use non-ionizing radiation. As a result, serial assessments can easily be performed to gauge response to treatment. Given their portability, limited power requirements, and instant access to imaging, they are the preferred modality for many remote clinical settings.

Thoracic ultrasonography allows rapid, accurate assessment for acute pulmonary edema at the bedside (Fig. 136.4). The presence of “lung comet tails” (also called B-lines) on thoracic ultrasound indicated extravascular water, are reproducible, quantifiable and have been inversely correlated with oxygen saturation and clinical status in HAPE patients. The use of ultrasonography to estimate pulmonary artery pressure is an emerging modality in the early detection and diagnosis of HAPE. Demonstration of high pulmonary artery pressures with normal left ventricular function is associated with HAPE and HAPE susceptibility.

**Chest Radiographs**

Other thoracic imaging options include chest radiographs. In HAPE patients, chest films reveal alveolar infiltrates, patchy in distribution, with areas of clearing between the patches. Unilateral infiltrates may be present in mild cases; however, bilateral infiltrates are seen in more advanced cases, with involvement of the right mid-lung field being most common (Fig. 136.5). Pleural effusion is rare but may be present in severe cases. The extent of the edema on the chest radiograph roughly parallels the clinical severity. Of note, the radiographic findings of cardiomegaly, bat-wing distribution of infiltrates, and Kerley B lines, which are typical of cardiogenic pulmonary edema, are absent in cases of HAPE.
Radiographic evidence of HAPE clears rapidly after initiation of treatment; some mild cases may clear in 4 to 6 hours, and most clear by 24 hours. Radiographs of patients with severe HAPE may reveal infiltrates that persist for as long as 2 weeks, even though the clinical symptoms have resolved.

**Electrocardiogram and Echocardiogram**

An electrocardiogram reveals tachycardia and evidence of right-sided heart strain, including right axis deviation, P wave abnormalities, tall R waves in the precordial leads, and S waves in the lateral leads. Hemodynamic studies reveal increased pulmonary vascular resistance, elevated pulmonary artery pressures, and normal pulmonary wedge pressures. Echocardiographic studies demonstrate high estimated pulmonary artery pressures, pulmonary vascular resistance, and normal left ventricular function.

**Management**

In remote settings, where oxygen and medical expertise may be unavailable, immediate descent to treat HAPE may be lifesaving. Delay of descent (eg, waiting hours for rescue personnel to initiate evacuation) can lead to rapid HAPE progression and can prove fatal. Descents of 3000 feet are generally adequate for a rapid recovery; however, descent should continue until symptoms resolve.

**Oxygen Therapy**

To minimize cold- or exercise-induced pulmonary hypertension, HAPE patients should be kept warm and should minimize exertion (Fig. 136.6). Patient with mild cases of HAPE under expert supervision have been successfully treated at altitude with oxygen, medications, and 1 or 2 days of bed rest. Oxygen administration increases the rate of improvement. Moderate cases can be treated without descent if bed rest, experienced providers, and adequate supplies of supplemental oxygen are available. Any treatment plan that does not include descent necessitates serial examinations by clinicians with experience in management of high-altitude illness.

If difficult terrain or weather conditions hamper efforts to descend, oxygen administration (or hyperbaric therapy) can be a lifesaving measure. Rescue personnel should air drop oxygen.
simulates a descent of 4000 to 5000 feet at moderate altitudes, and at the summit of Mt. Everest it would simulate a descent of approximately 9000 feet. These devices can be lifesaving in patients with HAPE and HACE. Some non-ambulatory patients are able to descend under their own power after a few hours in hyperbaric chambers.

Nifedipine

Although oxygen and descent remain the mainstays in treatment of HAPE, medications that lower pulmonary artery pressure, pulmonary blood volume, and pulmonary vascular resistance or enhance alveolar fluid clearance may be useful adjuncts. Unlike pulmonary edema secondary to acute CHF, HAPE does not result from excessive intravascular volume or failed cardiac pump function. As such, diuretic therapy has no role in the treatment of HAPE and may further exacerbate volume loss in patients who are already intravascularly depleted.19

Many pharmacotherapies used for HAPE treatment derive their limited authority from their demonstrated abilities to prevent HAPE. One of the better studied agents for both prophylaxis and treatment of HAPE is the calcium channel blocker, nifedipine. Acting as a pulmonary vasodilator, nifedipine is especially useful when oxygen is unavailable or descent is impossible. Nifedipine does not improve pulmonary hemodynamics as much as oxygen or descent do, and it does not have an additive effect when it is administered with oxygen. Treatment with 30 mg of a slow-release nifedipine preparation administered twice daily is effective. Patients should be monitored for the development of hypotension during nifedipine administration.

Other Medications

Although phosphodiesterase type 5 inhibitors (including tadalafil and sildenafil) are known to be useful for HAPE prevention, are widely used, and are unlikely to cause acute harm in this indication, they remain unstudied for HAPE treatment. Alveolar fluid clearance is upregulated by beta-adrenergic agonists in animal models, and inhaled beta-agonists have been used anecdotally for therapy of HAPE (salmeterol 125 µg inhaled twice daily).

The mainstay of HAPE treatment remains immediate oxygen (if it is available) and descent. Should these treatments not be available, nifedipine should be initiated. No compelling evidence suggests the concurrent use of these medications with oxygen has additional benefit beyond the use of oxygen alone.

Disposition

Mild to moderate cases of HAPE can be treated with oxygen, rest, and careful monitoring. Experienced physicians in recreational areas at moderate altitudes (eg, Colorado ski resorts) administer oxygen and observe HAPE patients to ensure adequate oxygenation. These patients are then discharged to their hotel with supplemental oxygen and monitored for improvement or deterioration. In severe HAPE, or milder cases that do not improve with therapy, descent is warranted. Rapid recovery is usually seen after descent to lower altitudes, and observation of the patient in the emergency department to ensure adequate room air oxygenation is generally adequate. On occasion, admission to the hospital is indicated to maintain the SaO₂ greater than 90%. In the hospital, continuous positive airway pressure improves gas exchange in HAPE patients. Hypocapnia, alkalosis, and radiographic evidence of HAPE may persist for several days. Thoracic ultrasound allows for frequent reassessments and has been shown to closely follow resolving edema and increasing oxygen saturations.

After oxygen saturation remains greater than 90% on room air and clinical improvement is apparent, the patient can be
which can range from mild emotional lability or confusion, to signs include ataxia, slurred speech, and altered mental status, as well as those of HAPE (cough and dyspnea) are often present. The symptoms of severe AMS (headache, fatigue, and vomiting) can progress to severe HACE with coma in as few as 12 hours. HACE is the least common but most severe form of high-altitude illness.17

Clinical Features

As with all forms of serious altitude illness, two key teaching points are the most effective means of prevention and must be understood by the patient: (1) a gradual or staged ascent to allow sufficient time to acclimatize is critical, and (2) immediate cessation of further ascent at the onset of symptoms can be lifesaving. Individuals with a prior history of HAPE should also avoid extreme exertion during the first 2 days at altitude. With a prior history of HAPE, prophylactic therapy should be considered. The preferred medication for HAPE prevention is the nonspecific pulmonary vasodilator medication nifedipine, 30 mg (controlled-release) two times daily before ascent and continued at altitude for 3 days. Less evidence exists to support the routine use of other pulmonary vasodilator medications for HAPE prevention.

Phosphodiesterase type 5 inhibitors are selective pulmonary vasodilators that increase cyclic guanosine monophosphate availability. Sildenafil (40 mg every 8 hours) and tadalafil (10 mg every 12 hours) are effective in preventing HAPE. The phosphodiesterase type 5 inhibitors have the added benefit that they are less likely than calcium channel blockers to induce systemic hypotension. A few additional medication options may be considered for prevention. Limited data suggest that dexamethasone (8 mg every 12 hours) started 2 days before ascent may prevent HAPE. Unpublished data from animal models revealed that dexamethasone decreases pulmonary capillary leakage through downregulation of the inflammatory cascade, decreasing alveolar fluid accumulation. To enhance alveolar fluid clearance, salmeterol 125 µg inhaled twice daily may be used as an adjunct to nifedipine in patients with a history of HAPE, although side effects are common at this high inhaled dose. Finally, clinical experience suggests that acetazolamide aids in acclimatization and prevents HAPE, and it has utility in reduction of hypoxic pulmonary vasoconstriction.

**HIGH-ALTITUDE CEREBRAL EDEMA**

**Principles**

HACE is the least common but most severe form of high-altitude illness (Box 136.6). Death from HACE at as low as 8200 feet is reported, although most cases occur above 12,000 feet. Mild AMS can progress to severe HACE with coma in as few as 12 hours. Although severe symptoms usually develop within 1 to 3 days, they may not occur until 5 to 9 days.

**Clinical Features**

HACE is characterized by evidence of global cerebral dysfunction. The symptoms of severe AMS (headache, fatigue, and vomiting) as well as those of HAPE (cough and dyspnea) are often present. Patient with HACE almost inevitably have had prior, unheeded symptoms of worsening AMS over hours to days. HACE-specific signs include ataxia, slurred speech, and altered mental status, which can range from mild emotional lability or confusion, to hallucinations and worsening obtundation that may advance to coma and death. Less commonly, generalized seizures and rarely, focal neurologic deficits may occur.

Altered mental status and cerebellar ataxia are the most sensitive signs for early recognition of HACE. The early appearance of ataxia reflects the particular sensitivity of the cerebellum to hypoxia. Ataxia alone is an indication for immediate descent. Retinal hemorrhages are common and rarely of clinical significance. Papilledema and occasionally cranial nerve palsy also occur in the setting of increased intracranial pressure.

**Differential Diagnosis**

Paroxysmal onset of symptoms should prompt consideration of other etiologies, such as hypothermia, hypoglycemia, CO poisoning, and acute cerebral vascular accidents (CVAs) (Box 136.7). A vascular lesion is suggested by abrupt onset, presence of a dense hemilateral palsy, a lack of preceding evidence of worsening high-altitude illness, or the persistence of signs despite adequate treatment of high-altitude illness.

**Diagnostic Testing**

Without advanced imaging, differentiating between HACE and acute CVA may be difficult. Although not common, the occurrence of cerebral thrombosis and transient ischemic attacks, in the absence of high-altitude illness, has been documented at high altitude. MRI of patients with HACE reveals white matter changes consistent with vasogenic edema (Fig. 136.8).

**Management**

Successful therapy for HACE requires early recognition and initiation of immediate descent. If available, high-flow oxygen should be initiated. Successful therapy for HACE requires early recognition and immediate descent. If available, high-flow oxygen should be initiated.

**High-Altitude Cerebral Edema Differential Diagnosis**

- Acute cerebral vascular accident (CVA)/transient ischemic attack
- Intracranial hemorrhage
- Hypoglycemia
- Carbon monoxide (CO) poisoning
- Meningitis/encephalitis
- Hypothermia
- Intracranial mass
- Vertebral/carotid dissection or stenosis
- Acute toxicidrome—alcohol, other
- Acute alcohol withdrawal/delirium tremens
- Seizure
- Transient global amnesia

**HIGH-ALTITUDE CEREBRAL EDEMA**

**Principles**

HACE is the least common but most severe form of high-altitude illness (Box 136.6). Death from HACE at as low as 8200 feet is reported, although most cases occur above 12,000 feet. Mild AMS can progress to severe HACE with coma in as few as 12 hours. Although severe symptoms usually develop within 1 to 3 days, they may not occur until 5 to 9 days.

**Clinical Features**

HACE is characterized by evidence of global cerebral dysfunction. The symptoms of severe AMS (headache, fatigue, and vomiting) as well as those of HAPE (cough and dyspnea) are often present. Patient with HACE almost inevitably have had prior, unheeded symptoms of worsening AMS over hours to days. HACE-specific signs include ataxia, slurred speech, and altered mental status, which can range from mild emotional lability or confusion, to hallucinations and worsening obtundation that may advance to coma and death. Less commonly, generalized seizures and rarely, focal neurologic deficits may occur.

Altered mental status and cerebellar ataxia are the most sensitive signs for early recognition of HACE. The early appearance of ataxia reflects the particular sensitivity of the cerebellum to hypoxia. Ataxia alone is an indication for immediate descent. Retinal hemorrhages are common and rarely of clinical significance. Papilledema and occasionally cranial nerve palsy also occur in the setting of increased intracranial pressure.

**Differential Diagnosis**

Paroxysmal onset of symptoms should prompt consideration of other etiologies, such as hypothermia, hypoglycemia, CO poisoning, and acute cerebral vascular accidents (CVAs) (Box 136.7). A vascular lesion is suggested by abrupt onset, presence of a dense hemilateral palsy, a lack of preceding evidence of worsening high-altitude illness, or the persistence of signs despite adequate treatment of high-altitude illness.

**Diagnostic Testing**

Without advanced imaging, differentiating between HACE and acute CVA may be difficult. Although not common, the occurrence of cerebral thrombosis and transient ischemic attacks, in the absence of high-altitude illness, has been documented at high altitude. MRI of patients with HACE reveals white matter changes consistent with vasogenic edema (Fig. 136.8).

**Management**

Successful therapy for HACE requires early recognition and initiation of immediate descent. If available, high-flow oxygen should be initiated.

**High-Altitude Cerebral Edema Differential Diagnosis**

- Acute cerebral vascular accident (CVA)/transient ischemic attack
- Intracranial hemorrhage
- Hypoglycemia
- Carbon monoxide (CO) poisoning
- Meningitis/encephalitis
- Hypothermia
- Intracranial mass
- Vertebral/carotid dissection or stenosis
- Acute toxicidrome—alcohol, other
- Acute alcohol withdrawal/delirium tremens
- Seizure
- Transient global amnesia

**HIGH-ALTITUDE CEREBRAL EDEMA**

**Principles**

HACE is the least common but most severe form of high-altitude illness (Box 136.6). Death from HACE at as low as 8200 feet is reported, although most cases occur above 12,000 feet. Mild AMS can progress to severe HACE with coma in as few as 12 hours. Although severe symptoms usually develop within 1 to 3 days, they may not occur until 5 to 9 days.

**Clinical Features**

HACE is characterized by evidence of global cerebral dysfunction. The symptoms of severe AMS (headache, fatigue, and vomiting) as well as those of HAPE (cough and dyspnea) are often present. Patient with HACE almost inevitably have had prior, unheeded symptoms of worsening AMS over hours to days. HACE-specific signs include ataxia, slurred speech, and altered mental status, which can range from mild emotional lability or confusion, to hallucinations and worsening obtundation that may advance to coma and death. Less commonly, generalized seizures and rarely, focal neurologic deficits may occur.

Altered mental status and cerebellar ataxia are the most sensitive signs for early recognition of HACE. The early appearance of ataxia reflects the particular sensitivity of the cerebellum to hypoxia. Ataxia alone is an indication for immediate descent. Retinal hemorrhages are common and rarely of clinical significance. Papilledema and occasionally cranial nerve palsy also occur in the setting of increased intracranial pressure.

**Differential Diagnosis**

Paroxysmal onset of symptoms should prompt consideration of other etiologies, such as hypothermia, hypoglycemia, CO poisoning, and acute cerebral vascular accidents (CVAs) (Box 136.7). A vascular lesion is suggested by abrupt onset, presence of a dense hemilateral palsy, a lack of preceding evidence of worsening high-altitude illness, or the persistence of signs despite adequate treatment of high-altitude illness.

**Diagnostic Testing**

Without advanced imaging, differentiating between HACE and acute CVA may be difficult. Although not common, the occurrence of cerebral thrombosis and transient ischemic attacks, in the absence of high-altitude illness, has been documented at high altitude. MRI of patients with HACE reveals white matter changes consistent with vasogenic edema (Fig. 136.8).

**Management**

Successful therapy for HACE requires early recognition and initiation of immediate descent. If available, high-flow oxygen should be initiated.
be administered. Oxygen alone reduces intracranial blood flow at high altitude. Steroid therapy is recommended and may result in recovery from HACE without neurologic deficits. The initial dose of dexamethasone is 8 mg parenterally or orally in mild cases, followed by 4 mg every 6 hours.

Patients with severely altered levels of consciousness require tracheal intubation. All efforts should be made to increase oxygenation, both by increasing FiO₂ and barometric pressure by descent. Hyperventilation, diuretics (eg, furosemide), and hypertonic solutions (eg, mannitol) have been used to manage severely elevated intracranial pressure, but grave caution is warranted. Many patients with HACE are already volume depleted from poor fluid intake; diuretic use could compromise adequate intravascular volume and reduce cerebral perfusion pressure.

Hyperbaric treatment of HACE is also effective and may result in temporary improvement and allow self-rescue. Conversely, coma may persist for several days after descent to lower altitudes.

**Disposition**

Immediate descent should occur as soon as possible. Placing HACE patients in a hyperbaric device may only delay the more comprehensive care available in the hospital setting.

Long-term neurologic deficits including ataxia and cognitive impairment have been reported after recovery from acute episodes of HACE. Both transient and long-lasting neurobehavioral impairments can occur in mountaineers after climbing to extreme altitude without experiencing clinical HACE. Because of the potential for long-lasting neurologic injury, the clinician who treats high-altitude illness should be extremely sensitive to the early manifestations of HACE. Early treatment of HACE generally results in good outcomes, but after coma is present, the mortality rate exceeds 60%.

**SPECIAL CONSIDERATIONS**

**High-Altitude Retinal Hemorrhage**

High-altitude retinal hemorrhage (HARH) is the most common type of retinopathy in visitors to high altitude. These hemorrhages are common at altitudes above 17,500 feet, although they can occur at lower levels.

The exact incidence of HARH is unknown because most patients are asymptomatic, with HARH noted only on retinoscopy. HARH is not generally related to the presence of mild AMS but does seem to be related to strenuous exercise at high altitude. At any altitude, in the setting of severe HAPE or HACE, retinal hemorrhages are commonly noted, but the mechanism remains unclear.

Hemorrhages usually spare the macula (Fig. 136.9) and most often resolve without treatment in 2 or 3 weeks. With macular involvement, central scotomas may be noticed and only gradually resolve. In some cases, these visual defects are permanent. HARH is more likely to occur among individuals with a previous history of such hemorrhages. The underlying risk remains unclear. They usually do not pose a contraindication to return to high altitude unless the macular region is involved. Altitude related changes in intraocular pressure are not associated with AMS.

**Carbon Monoxide Poisoning**

CO poisoning can occur at altitude from the use of fires and combustion stoves to keep warm and to prepare food in the high-altitude environment. CO poisoning at altitude can be more
devastating because of preexisting hypobaria-induced hypoxia. As CO avidly binds to hemoglobin, it prevents oxygen transport and so exacerbates tissue hypoxia. CO poisoning and AMS are easy to confuse because of similar symptoms and signs, including headache, nausea, dizziness, dyspnea, and lassitude. If suspected, immediate assay of carboxyhemoglobin levels using co-oximetry or lab testing is indicated. Importantly, empirical treatment with oxygen and hyperbaria will benefit both conditions. If CO poisoning is suspected, immediate testing of the patient’s affected indoor space should occur before patient is discharged home. If testing is not available, the patient should leave the enclosed space and descend or use supplemental oxygen if it is available.

**ALTITUDE AND UNDERLYING MEDICAL CONDITIONS**

Individuals with preexisting diseases such as sickle-cell disease, moderate to severe chronic obstructive pulmonary disease (COPD) and coronary artery disease (CAD) may have a more difficult time acclimatizing, because these disease states may be aggravated by the hypoxic atmosphere at higher elevations. eBox 136.1 describes the risk associated with travel to altitude in individuals with a variety of underlying comorbidities.

**Respiratory Illnesses**

Travelers with COPD to have underlying anatomic and physiologic changes that predispose them to development of hypoxemia, sleep apnea, pulmonary hypertension, and ventilation disorders at even moderate altitudes. COPD is a risk factor for the development of AMS. Although oxygen saturation remains more than 90% in a healthy, awake individual until an altitude of 8000 feet, patients with COPD may desaturate below 90% at lower altitudes. High altitude increases hypoxic pulmonary vasoconstriction and may potentiate the development of cor pulmonale, which is known to adversely affect survival at sea level. Individuals with chronic COPD should be advised of the potential need for oxygen supplementation when traveling to moderate altitude, especially if they are already using oxygen at sea level or if dyspnea or fatigue becomes worse. Use of a pulse oximeter can guide the need for increased oxygen supplementation.

Patients with asthma, on the other hand, may have fewer problems at altitude because of decreased allergens and pollutants and decreased airflow turbulence. Even those with exercise-induced bronchospasm do not have worsening symptoms while exercising at 5000 feet. In addition, AMS incidence is not increased in asthmatics. People with asthma traveling to higher elevations should continue their usual medications and carry a rescue supply of bronchodilators and steroids.

Patients with asthma to ascend to high altitude with preexisting primary or secondary pulmonary hypertension should be considered HAPE susceptible, and those with primary pulmonary hypertension should be considered at increased risk for HAPE. Patients with known pulmonary hypertension should be advised against travel to higher elevations. If travel cannot be avoided, supplemental oxygen should be used. Prophylactic sustained-release nifedipine, 30 mg twice daily for the duration of the stay at altitude, can prevent HAPE. Phosphodiesterase type-5 inhibitors and steroids may also be used.

**Cardiovascular**

Individuals with a history of CHF, CAD, dysrhythmias, or coronary bypass surgery are infrequently studied in the high-altitude setting. In theory, people with diseased myocardium should be advised to avoid high altitude because of decreased environmental oxygen availability. No studies report increased mortality in visitors to these locations. To the contrary, long-term residents at high altitude may be protected from coronary artery disease (CAD) by increased collateral vessel formation or a decrease in the development of atherosclerosis.

All travelers have increased sympathetic activity on initial exposure to high altitude. In patients with heart disease, the resultant increase in heart rate and blood pressure increases cardiac work and myocardial oxygen consumption, which could increase angina symptoms and dysrhythmias. Although both cardiac rhythm abnormalities and ST segment and T wave electrocardiographic changes are reported, none of these changes are associated with clinical evidence of myocardial ischemia. Limited data suggest no increased risk for sudden cardiac death or myocardial infarction at altitudes up to 8000 feet. When individuals with stable angina are exercised, there is conflicting evidence for the probability of inducing malignant dysrhythmias. Travelers with heart disease who ascend to moderate altitudes do not appear to have an increased incidence of AMS.

Travelers with mild stable CAD should be advised to ascend gradually, to limit activity especially in the first few days at elevation, and to continue anti-anginal and antihypertensive medications. Individuals who have more severe, symptomatic coronary disease or those in a high-risk group (low ejection fraction, abnormal stress test results, and high-grade ventricular ectopy) should avoid travel to high altitudes. Ascent to moderate elevations can be suggested on an individual basis with the previously mentioned precautions. Individuals with heart failure who travel to altitude may require increased use of diuretics to promote diuresis and acclimatization. Acetazolamide prophylaxis may be useful to speed acclimatization and to prevent AMS and its accompanying fluid retention.

**Hypertension**

High-altitude travel produces a rapid, mild increase in blood pressure and heart rate in healthy individuals because of increased sympathetic tone. This increase is maximal at 2 or 3 weeks, and returns to baseline values over time because of a downregulation of adrenergic receptors if one stays at high altitude or on descent to sea level. No studies demonstrate an increased predisposition for altitude illness in patients with underlying hypertension.

The incidence of hypertension in sea-level dwellers traveling to high altitude is 10% to 25%. On travel from sea-level to low altitudes (3000 feet), no differences are noted in either normotensive or hypertensive individuals. Above 9000 feet, more significant increases may occur. This suggests that people with severe hypertension should travel to high altitude only under careful monitoring. For individuals who have mild preexisting hypertension, additional treatment is not routinely necessary. Patients with moderate hypertension should be monitored frequently in the first few days at altitude and antihypertensive medications continued. For hypertensive patients with a rapid rise in blood pressure and who will be staying for several weeks, an alpha-blocker, nifedipine, or angiotensin-converting enzyme inhibitor should be considered.

**Seizures**

Numerous reports of altitude-provoked seizures exist, but epidemiologic data are lacking. Seizures attributable to high altitude are typically generalized tonic-clonic in nature. A focal seizure at altitude should prompt a thorough evaluation for a space-occupying lesion. Several pathophysiologic mechanisms are implicated. These include sleep deprivation from periodic breathing, hyperventilation, and the direct effect of hypobaric hypoxia. These mechanisms are postulated to induce a metabolic state that lowers the seizure threshold. Seizures not responding to
Risk Associated With Travel to Altitude in Individuals With a Variety of Underlying Comorbidities

**ADVISABILITY OF EXPOSURE TO HIGH ALTITUDE FOR COMMON CONDITIONS (WITHOUT SUPPLEMENTAL OXYGEN)**

**Probably No Extra Risk**
- Young and old
- Fit and unfit
- Mild obesity
- Diabetes
- Previous coronary artery bypass grafting (without angina)
- Mild chronic obstructive pulmonary disease (COPD)
- Asthma
- Low-risk pregnancy
- Controlled hypertension
- Controlled seizure disorder
- Psychiatric disorders
- Neoplastic diseases
- Inflammatory conditions

**Caution**
- Moderate COPD
- Asymptomatic pulmonary hypertension
- Compensated congestive heart failure (CHF)
- Morbid obesity
- Sleep apnea syndromes
- Troublesome arrhythmias
- Stable angina or coronary artery disease (CAD)
- High-risk pregnancy
- Sickle cell trait
- Cerebrovascular diseases
- Any cause of restricted pulmonary circulation
- Seizure disorder (not taking medication)
- Radial keratotomy

**Contraindicated**
- Sickle cell anemia (with history of crises)
- Severe COPD
- Symptomatic pulmonary hypertension
- Uncompensated CHF

Pregnancy-induced hypertension, proteinuria, and peripheral edema (manifestations of toxemia and preeclampsia) are more common at high altitudes and may also be related to maternal and uterine hypoxemia. Although hypertension in pregnancy is more common at high altitudes, no evidence exists for an increase in spontaneous abortions, abruptio placentae, or placenta previa.

Travel by pregnant women to moderate altitudes appears to be safe, but caution is advised for lowland women with normal pregnancies who wish to travel above 13,000 feet, for pregnant women who wish to remain at high altitude for a prolonged period, and for women with complicated pregnancies.

Radial Keratotomy

Patient with a history of radial keratotomy may experience hyperopic (farsighted) visual changes with ascent above 9000 feet. This results from corneal swelling from ambient hypoxia because the cornea is markedly sensitive to both systemic and ambient oxygen tension. In normal corneas, this swelling is uniform. After radial keratotomy, the swelling is exacerbated and inconsistent secondary to the pattern of the incisions. Photorefractive keratotomy and LASIK, which use laser techniques that do not produce incisions but instead shave the cornea and corneal stroma, respectively, do not result in similar problems.

ACKNOWLEDGMENT

The authors would like to acknowledge Dr. Paul Barre for his work on this edition and to Drs. Benjamin Honigman, Michael Yaron, Ryan D. Paterson, and Christopher B. Davis for their contributions to previous editions of this chapter.
CHAPTER 136: QUESTIONS & ANSWERS

136.1. Which of the following individuals has the highest risk of developing high-altitude pulmonary edema (HAPE), assuming all are generally healthy, live at the same altitude, and travel to the same altitude?  
A. A 16-month-old boy  
B. A 19-year-old man  
C. A 19-year-old woman  
D. A 42-year-old man  
E. A 42-year-old woman  

**Answer:** B. Many factors contribute to the development of HAPE including total altitude, sleeping altitude, time at altitude, previous acclimatization, and the presence of comorbidities. However, in general, both females and the elderly are less likely to develop HAPE. Also, whereas younger males are more at risk, HAPE is extremely rare in individuals younger than 2 years old regardless of gender.

136.2. Which of the following symptoms must be present to establish a diagnosis of acute mountain sickness (AMS)?  
A. Dizziness  
B. Fatigue  
C. Headache  
D. Insomnia  
E. Nausea  

**Answer:** C. To diagnose AMS, a patient must have a recent gain in altitude, be at that altitude for several hours, and have a headache. In addition, at least one of the following must also be present: gastrointestinal upset, fatigue, dizziness or light-headedness, or difficulty sleeping.

136.3. Which of the following medications used to treat acute mountain sickness (AMS) actually accelerates acclimatization?  
A. Acetazolamide  
B. Aspirin  
C. Dexamethasone  
D. Oxygen  
E. Prochlorperazine  

**Answer:** A. Acetazolamide is a carbonic anhydrase inhibitor and induces a metabolic acidosis that results in increased ventilation. Aspirin is an appropriate treatment for the headache associated with AMS. Dexamethasone and oxygen both improve all symptoms of AMS but do not aid acclimatization. Prochlorperazine is appropriate treatment for the gastrointestinal upset caused by AMS and is preferred over promethazine because it does not depress the respiratory centers.

136.4. Which of the following conditions occurs more commonly at high altitude?  
A. Congestive heart failure (CHF)  
B. Myocardial infarction  
C. Pericarditis  
D. Pneumothorax  
E. Pulmonary embolism (PE)  

**Answer:** E. Altitude causes hypercoagulability from hyperviscosity due to elevated hematocrit and dehydration. Venous stasis is also more common at altitude due to the relative immobility of sleeping in confined spaces (sleeping bags and small tents). Together, these facts lead to an increased risk of PE. Occasionally, PE may be misdiagnosed as high-altitude pulmonary edema (HAPE) and treated inappropriately.

136.5. High-altitude pulmonary edema (HAPE) can be difficult to distinguish from acute mountain sickness (AMS). Although the pathophysiology of each is similar, the treatment and prognosis are different. Which of the following features is indicative of HAPE as opposed to AMS?  
A. Diuresis  
B. Dyspnea at rest  
C. Headache  
D. Lower-extremity edema  
E. Symptom onset soon after arrival at altitude  

**Answer:** B. Dyspnea on exertion is nearly universal at altitude and is not indicative of a pathologic process, but dyspnea at rest is not normal and is an early symptom of HAPE. Cough is common at
altitude or any time when one breathes cold dry air. Fluid retention and peripheral edema are common manifestations of AMS, whereas a diuresis can be a sign of acclimatization. Neither AMS nor HAPE commonly occurs soon after arrival at altitude, with AMS usually occurring within 24 hours and HAPE usually occurring in 2 to 4 days.

136.6. The definitive treatment for high-altitude pulmonary edema (HAPE) is oxygen and descent to lower altitudes. Which of the following medications is also useful in the treatment of HAPE?
   A. Hydrochlorothiazide
   B. Metoprolol
   C. Nifedipine
   D. Nitroglycerin
   E. Verapamil

**Answer:** C. Nifedipine is a nonselective pulmonary vasodilator and is useful in the treatment and prevention of HAPE. Sildenafil and tadalafil may also be useful in the prevention of HAPE. These phosphodiesterase-5 inhibitors increase cyclic guanosine monophosphate availability and result in pulmonary vasodilation.

136.7. Which of the following signs or symptoms is specific for high-altitude cerebral edema (HACE) as opposed to acute mountain sickness (AMS) or high-altitude pulmonary edema (HAPE)?
   A. Ataxia
   B. Dizziness
   C. Dyspnea
   D. Headache
   E. Vomiting

**Answer:** A. Ataxia, seizures, slurred speech, focal neurologic deficits, and altered mentation are all specific to HACE. Dizziness, headache, and vomiting can all be seen in AMS. Dyspnea is nearly universal in HAPE.

136.8. You are the doctor on a group expedition to Denali. Recently, some of the climbers have complained of headaches, dyspnea, nausea, and difficulty sleeping. At breakfast this morning, one of the climbers is noted to have difficulty speaking and some slurred speech, which he attributes to a restless night’s sleep. What treatment is appropriate for this patient?
   A. 24 hours of rest before further ascent
   B. Acetazolamide
   C. Descent to lower altitude
   D. Nifedipine
   E. Oxygen

**Answer:** C. This patient has high-altitude cerebral edema (HACE). Any hard neurologic finding (ataxia, slurred speech, focal neurologic deficits, seizure, or altered mentation) at altitude is indicative of HACE. Unlike acute mountain sickness (AMS) or high-altitude pulmonary edema (HAPE), which can occasionally be treated without descent, descent is mandatory for all cases of HACE. Dexamethasone should also be given to all patients with HACE. The other treatments mentioned are all possible treatments for HAPE.

136.9. You are the doctor on a group expedition to Denali and are currently at an elevation of 10,000 feet. One of the members of the group experiences headache, lightheadedness, and nausea. You diagnose him with acute mountain sickness (AMS) and treat him with acetazolamide and oxygen. He wants to know when he can continue climbing the mountain. What do you tell him?
   A. You may ascend if your oxygen saturation (as measured by pulse oximetry) is higher than 90%.
   B. You may ascend when all your symptoms resolve.
   C. You may never ascend any higher than this altitude.
   D. You may not ascend any higher on this expedition but may try again in 1 or 2 months.
   E. You may only sleep 1000 feet higher than your current altitude.

**Answer:** B. Management of AMS must adhere to the axiom, “After the symptoms of altitude illness occur, further ascent to a higher sleeping altitude is contraindicated.”
PRINCIPLES

Definitions

Traditionally, the terminology describing drowning injuries has been confusing and impractical. In the past, *drowning* referred to death within 24 hours of suffocation from submersion in a liquid, whereas *near-drowning* described victims who survived at least 24 hours past the initial event regardless of the outcome. In 2005 the World Health Organization (WHO) published a new policy defining drowning to clarify documentation and to better track drowning injuries worldwide. Drowning was defined as “the process of experiencing respiratory impairment from submersion/immersion in liquid.” Furthermore, the WHO policy states, “Drowning outcomes should be classified as: death, morbidity, and no morbidity; the terms wet, dry, active, passive, silent, and secondary drowning should no longer be used.” The term *near-drowning* should not be used, and the association of the term **near-drowning with a fatal outcome** should be abandoned.

Immersion syndrome refers specifically to syncope resulting from cardiac dysrhythmias on sudden contact with water that is at least 5°C lower than body temperature. The risk is proportional to the difference between body temperature and water temperature. Wetting of the face and head before entrance into the water may prevent the inciting sequence of events. Putative mechanisms for the syndrome are vagal stimulation leading to asystole and ventricular fibrillation secondary to QT prolongation after a massive release of catecholamines on contact with cold water. The resultant loss of consciousness leads to secondary drowning.

Epidemiology

Each year an estimated 350,000 people die of drowning worldwide, a rate of 40 individuals an hour, most of whom are children. Low- and middle-income countries account for more than 90% of all drowning deaths and a disproportionate share of years of life lost. Drowning is among the top ten causes of mortality for children and young people worldwide. In Bangladesh it accounts for 43% of deaths in children 1 to 4 years old.

In the United States drowning is the tenth most common cause of unintentional death, accounting for 3391 deaths (1.1 per 100,000) in 2013. Among children 1 to 4 years old, drowning is the leading cause of injury mortality; for 5- to 14-year-olds, it is second only to motor vehicle crashes.

The incidence of drowning with nonfatal outcomes is unknown. The Centers for Disease Control and Prevention (CDC) estimates that for every child who dies by drowning in the United States, another five receive emergency department (ED) care for a drowning event, and half of these children require hospitalization. Among all age groups, an estimated one to four hospitalizations secondary to nonfatal drownings occur for every drowning death. The economic implications of drowning injuries are profound. In Australia, drowning has the highest average lifetime cost ($40,071 in US currency) of any injury type.

Drownings occur in domestic settings such as swimming pools, hot tubs, bathtubs, large buckets, and rainwater tanks and in all forms of natural bodies of water. A review of all drowning deaths among individuals younger than 20 years old in the United States during a 1-year period revealed that 55% of infants younger than 1 year old drowned in bathtubs, and nearly 16% drowned in large household buckets. Most (56%) children 1 to 4 years old drowned in artificial pools, whereas most (63%) deaths among older children occur in natural bodies of fresh water.

Because of the recent natural disasters, the incidence of drowning injuries and fatalities is rising. In disasters such as floods and tsunamis, older populations are disproportionately affected. A study from hurricane Katrina found that 49% of fatalities were in people 75 years old or older.

Risk Factors

Age, gender, and race affect incidence of drowning. Toddlers and those over 75 years old are at greatest risk of death by drowning, with annual incidences of 2.1 and 1.3 per 100,000, respectively. Boys account for almost 80% of victims older than 1 year old. American Indian and Alaska Native children between 1 and 4 years old have the highest annual incidence of drowning mortality (3.83 per 100,000), and black teenagers between 11 and 12 years old drown in swimming pools at ten times the rate of white children of the same age. The risk of death by drowning for all ages of the American Indian and Alaska Native population is 80% higher than the United States population as a whole.

Ethanol consumption in proximity with water is a major risk factor for drowning. Acute ethanol intoxication may be a contributing factor in 30% to 50% of drownings among adults and adolescents. An association has established between blood ethanol concentration (BEC) and risk of death from drowning while using watercraft. The odds ratios of fatality from drowning follow a trend from 2.8 for a BEC of 1 to 49 mg/dL to 37.4 for a BEC of 150 mg/dL or greater compared with sober case controls.

Drowning in the United States follows clear temporal patterns. Two-thirds of pediatric deaths occur between May and August. Drowning injuries are 48% more likely to occur on weekends than weekdays and drowning victims older than 20 years old are most often participating in water sports or using watercraft.

The relationship between swimming ability and the risk of drowning is unclear. No direct evidence exists to suggest that inexperienced swimmers are more likely to drown. On the contrary, skilled swimmers have greater exposure to water and may be more prone to drowning incidents.

Numerous medical conditions confer an increased likelihood of drowning injury. Seizure disorders increase the chance of drowning among children and adolescents nearly 20 times. Ten percent of deaths in a cohort of patients with seizures followed for 40 years were due to drowning. Autism and other developmental and behavioral disorders increase risk in children as well. Immersion in cold water extends the QT interval, thus increasing the risk of dysrhythmias in individuals with prolonged QT syndrome at baseline.
Pathophysiology

Unexpected submersion triggers breath-holding, panic, and a struggle to surface. Air hunger and hypoxia develop, and the victim begins to swallow water. As breath-holding is overcome, involuntary gasps result in aspiration. The quantity of fluid aspirated, rather than the composition, determines subsequent pulmonary derangement. The pathophysiologic differences between freshwater and saltwater aspiration with respect to resultant electrolyte imbalance, hemolysis, and fluid compartment shifting do not occur until the amount of aspirated water is significantly more than the typical drowning victim aspirates. In one review of the hospital treatment of drowning victims, no patient required emergent intervention for a significant electrolyte abnormality. Aspiration of 1 to 3 mL/kg of either fresh water or salt water destroys the integrity of pulmonary surfactant, leading to alveolar collapse, atelectasis, noncardiogenic pulmonary edema, intrapulmonary shunting, and ventilation-perfusion mismatch. Profound hypoxia and metabolic and respiratory acidoses ensue, leading to cardiovascular collapse, neuronal injury, and ultimately death.

The classic hypothesis was that 10% to 15% of drowning victims die without aspiration of a significant amount of water. Death from such dry drowning putatively results from severe laryngospasm causing hypoxia, convulsion, and death without entry of fluid into the lungs. An exhaustive review of the literature failed to corroborate this hypothesis. Dry drownings more appropriately reflect deaths from causes other than simple submersion.

Many factors may influence the pathophysiologic sequence of events in drowning and affect the chance of survival, including age, water temperature, duration and degree of hypothermia, diving reflex, and effectiveness of resuscitative efforts. Children have a lower ratio of body mass to surface area and, therefore, develop hypothermia more quickly and to a greater degree after immersion in cold water than adults do. Hypothermia lowers cerebral metabolic rate and is neuroprotective to some extent for victims of submersion injury. Despite dramatic case reports of patients surviving prolonged submersion in cold water with full neurologic recovery, hypothermia is generally a poor prognostic finding. Cold-water immersion speeds the development of exhaustion, altered consciousness, and cardiac dysrhythmia. The diving reflex may also play a protective role in infant and child submersion. Activation of the diving reflex by fear or immersion of the face in cold water shunts blood centrally to the heart and brain. Apnea and bradycardia ensue, prolonging the duration of submersion tolerated without central nervous system (CNS) damage. The proposed protective effect of cold water immersion was unfortunately not seen in a study of 1094 drowning victims of all ages, where water temperature had no correlation.

CLINICAL FEATURES

History and Physical Examination

Many drowning episodes are witnessed. Toddler drownings are an important exception, however, often occurring because of a lapse in supervision. Signs of pulmonary injury may be obvious in a drowning victim who is hypoxic, cyanotic, and in respiratory distress or arrest. More subtle clues, such as increased respiratory rate and audible rhonchi, rales, or wheezes, should alert the clinician to evolving respiratory compromise. Drowning victims swallow a significantly greater volume of water than is aspirated, and gastric distention from positive-pressure ventilation during rescue is common. As a result, 60% of patients vomit after a drowning event. Aspiration of gastric contents greatly compounds the degree of pulmonary injury and increases the likelihood that acute respiratory distress syndrome (ARDS) will ensue. In addition, aspiration of particulate contaminants such as mud, sewage, and bacteria may obstruct the smaller bronchi and bronchioles and greatly increase the risk of infection (both bacterial and fungal in nature).

Victims with CNS injury may present with symptoms ranging from mild lethargy to coma with fixed and dilated pupils. CNS injury results from the initial hypoxic or ischemic insult and from the cascade of reperfusion injury that follows reestablishment of cerebral blood flow after an arrest. The release of inflammatory mediators and the generation of oxygen free radicals in the postresuscitative period contribute to cytotoxic cerebral edema, compromise of the blood-brain barrier, and increased intracranial pressure.

Cardiac dysrhythmias may incite drowning or develop as its consequence. Hypoxemia, acidosis, and, potentially, hypothermia are the primary factors responsible for dysrhythmias ranging from ventricular tachycardia and fibrillation to bradycardia-asystole. Electrolyte disturbances are rarely significant enough to be dysrhythmogenic.

Other clinical sequelae of drowning may include acute renal impairment, which is present on admission in approximately 50% of patients as the result of lactic acidosis; prolonged hypoperfusion; and, in some instances, rhabdomyolysis. Coagulopathy as a consequence of associated hypothermia or disseminated intravascular coagulation (DIC) may also occur.

Prognostic Factors

Many factors help predict patients who will survive a drowning injury neurologically intact. Hypoxia, which is usually dependent on submersion time, is the most important factor related to outcome and subsequent quality of life in drowning victims. Drowning victims who arrive in the ED alert with normal hemodynamics are unlikely to experience neurologic impairment. Circumstantial variables that portend a poor outcome include victim age younger than 3 years old, submersion for longer than 5 to 10 minutes, and initiation of cardiopulmonary resuscitation (CPR) more than 10 minutes after rescue. Adverse neurologic findings on initial presentation do not preclude full neurologic recovery, although in general, patients whose duration of submersion or resuscitation exceeds 10 minutes have an unfavorable outcome. With the exception of victim age, however, such measurements are generally either unknown or inaccurately estimated at the time of a patient’s arrival in the ED. On arrival, objective findings associated with an unfavorable prognosis include hypothermia, severe acidosis, unreactive pupils, a Glasgow Coma Scale score of 3, and asystole or the need for ongoing CPR. Neurologically intact survival is reported for individual patients even with several of these factors present; none of several proposed scoring systems using combinations of these variables has 100% predictive power.

Children who present with an abnormal head computed tomography (CT) scan (eg, intracranial bleed, cerebral edema) within the first 24 hours have a nearly 100% mortality rate. Furthermore, an abnormal head CT scan at any time is associated with poor outcome (death or persistent vegetative state).

DIFFERENTIAL DIAGNOSIS

The precipitants of a drowning, such as drug or ethanol intoxication, cardiac arrest, hypoglycemia, seizure, and attempted suicide or homicide, should be considered in patients found unresponsive in water. For pediatric victims, child abuse or neglect should also be considered a potential cause. Potential head or cervical spine injury is an important consideration in drowning associated with trauma.
DIAGNOSTIC TESTING

Cardiac monitoring and an electrocardiogram (ECG) should be obtained to determine the presence of significant dysrhythmias, QT prolongation, or ischemia. Pulse oximetry, capnography, and arterial blood gases should be monitored closely in all drowning victims for signs of hypoxemia, hypercarbia, and acidosis. Blood glucose, serum creatinine, and electrolyte values should be obtained, although serum creatinine concentration and electrolyte levels are usually normal on initial presentation. Similarly, complete blood count is often normal with the exception of leukocytosis. Serum ethanol levels and urine toxicology screening may be appropriate for illicit drugs, depending on the circumstances of the drowning. Subsequently, evidence of renal failure, hepatic dysfunction, and DIC may be noted on laboratory testing.

The initial chest radiograph is often unreliable and may underestimate the severity of pulmonary injury. Infiltrates or pulmonary edema may be evident within hours; therefore, repeat radiographs are indicated with persistent respiratory symptoms. Initial chest radiographs are often unreliable even in the setting of serious and evolving pathologic processes. In symptomatic patients, frequent arterial blood gas measurements are indicated to monitor rapidly changing respiratory function.

Electroencephalography should be assessed for seizure activity should be considered in the obtunded drowning victim. Cranial CT is rarely initially contributory unless significant trauma or other pertinent injury is suspected. Magnetic resonance imaging (MRI) of the brain may predict neurologic outcome after drowning, but its prognostic value is not optimal until 3 or 4 days elapse.

MANAGEMENT

Salient details of the events surrounding the incident should be ascertained rapidly. Resuscitation of pulseless and apneic patients should be attempted initially in most cases because bystander estimates of total submersion time are often inaccurate. The clinical presentation of severe hypothermia often mimics death, and functional recovery is possible for hypothermic individuals submerged for significant periods of time.

For a victim without vital signs, outcome depends on the interval preceding CPR. Because these are hypoxic driven cardiac arrests, this is one situation where compression-only CPR may be as effective as CPR with assisted ventilation, although this has not been well studied. Mouth-to-mouth ventilation while in the water should be attempted but not at the cost of prolonging the extrication. Chest compressions are impractical before extrication but should be initiated as soon as the individual is placed on a solid surface, such as a poolside or beach.

Cervical spine injuries are rare in drowning victims. Patients more likely to have cervical spine injuries tend to have either clinical signs of serious trauma or a history of motor vehicle crash, fall from height, or diving into the water. Unless such factors are present, routine cervical spine immobilization for submersion victims is not warranted.

On arrival in the ED, cardiac monitoring and continuous pulse oximetry should be established. A core temperature obtained with a low-reading probe is indicated for any unstable or lethargic patient. Values obtained by use of infrared ear thermometry are unreliable in drowning victims.8 Rewarming of a hypothermic patient may suffice for hemodynamic stabilization and improvement in mental status. A spontaneously breathing patient should be monitored for signs of developing pulmonary injury.

Clinical impression and objective determination of the adequacy of oxygenation and ventilation should determine the decision for tracheal intubation. Apparent or developing respiratory distress, absence of protective airway reflexes, and significant associated head or chest injuries are indications. A partial pressure of carbon dioxide in the arterial blood \( \text{PaCO}_2 \) greater than 50 mm Hg should prompt strong consideration of intubation and lung protective ventilation. Patients unable to maintain oxygen saturation greater than 90%, or with an oxygen in arterial blood \( \text{PaO}_2 \) greater than 60 mm Hg on high-flow oxygen, require positive airway pressure to increase functional residual capacity, to decrease intrapulmonary shunting, and to reduce ventilation-perfusion mismatch. In awake patients, this may be accomplished by face or nasal mask (continuous positive airway pressure), but the risk of potential gastric distention, vomiting, and aspiration should be considered. Otherwise, tracheal intubation and lung protective ventilation with positive end-expiratory pressure are indicated. The hemodynamic consequences of positive end-expiratory pressure should be monitored carefully, because increased intrathoracic pressure may compromise venous return and cardiac output. Decreased cranial venous return may impede cerebral perfusion.

No consensus exists with regard to the appropriate length of resuscitative effort for hypothermic drowning victims in the ED. The safest parameter is to continue until the core temperature reaches at least 32°C to 35°C, because cerebral death cannot be diagnosed accurately in hypothermic patients with temperatures below this level. This parameter may not always be practical, however, because brain-dead patients are often poikilothermic.

The administration of corticosteroids in the setting of drowning and potential ARDS does not improve outcome. Barbiturate-induced coma, diuresis, neuromuscular blockade, and hyperventilation do not improve neurologic outcome and, particularly in the case of hyperventilation, may be harmful. Similarly, empirical antibiotics do not increase survival and should be administered only to the patient who was submerged in grossly contaminated water or who shows signs of infection or sepsis.

Interventions, such as induced or permissive hypothermia, aimed at attenuation of reperfusion injury after anoxic brain insult are the focus of intense investigative effort. Drowning victims in cardiac arrest are usually colder than 30°C and require warming. Comatose patients who have been resuscitated after reasonable submersion time regardless of rhythm should not be rewarmed above 34°C. Rewarming only up to 34°C followed by a 24-hour mild hypothermic treatment before normothermia is reached may be advantageous because of decreased pulmonary reperfusion injury and reduced secondary brain injury. Emerging resuscitation literature indicates an emerging role for therapeutic hypothermia in drowning victims.

DISPOSITION

Symptomatic patients should be admitted for treatment. Patients with a history of apnea, unconsciousness, intoxication, or hypoxia and any patients who manifest dysrhythmias or an abnormal chest radiographs also require admission. Patients who are asymptomatic on presentation to the ED, maintain normal room air oxygen saturation, and have no chest radiograph or arterial blood gas abnormalities can be discharged safely after an observation period of 6 hours. Careful instructions about symptoms or signs of delayed pulmonary complications are necessary, and the patient should be discharged in the care of a competent adult.

Preventive Efforts

The mortality rate from drowning has been decreasing since the 1990s in the United States. A similar downward trend in submersion injuries is reported in Great Britain. In low income countries globally, drowning deaths (particularly in children) are on the rise. Although the exact causes of this decline are unknown, an
increased public awareness of preventive measures and an emphasis on public education with regard to CPR and the dangers of ethanol use in conjunction with water-related activities are contributing significantly to the reduction in fatalities, in some locations by over 80%.

Parental education about the danger of pediatric drowning is an important focus of preventive efforts. Inadequate supervision of children playing in or near water is one of the most common causes of pediatric submersion death, underscoring the importance of increasing awareness of the need for constant oversight of children in this setting. Most pediatric submersion injuries in swimming pools occur at the victim’s home. In most cases, the child is last seen in the house, is left unattended for a moment, and enters the pool on an unfenced side closest to the home with no audible splash or screaming. Adequate and fully circumferential fencing of residential pools is a current recommendation of the American Academy of Pediatrics (AAP). Drowning or submersion is 3.7 times more likely in a non-fenced pool than in a properly fenced pool. In Australia, safety legislation is associated with a 30% reduction in drowning rates in young children. Unfortunately, legislation requiring appropriate fencing is poorly adhered to, and only 40% of households are compliant.

Legislation requiring personal floatation device usage in recreational boaters in Australia resulted in a significant decrease in drowning deaths.\textsuperscript{10}

Effective approaches to prevention efforts in low- and middle-income countries differ from those in high-income countries. Data from almost 100,000 children in Bangladesh either entered into swim lessons or kept in a common supervision area in the community showed relative risks of drowning of 0.072 and 0.181, respectively. Both interventions were found to be extremely cost effective.\textsuperscript{11}

Medical care providers are a vital resource for enhancement of public awareness of the importance of these measures. The literature supports the concept that education in the ED about drowning prevention can have a positive impact on patient and family awareness of steps to lessen the likelihood of catastrophic drowning injury.

### KEY CONCEPTS

- Drowning is a leading cause of death and loss of years of life with over 90% of cases occurring in lower- and middle-income countries. Cost-effective prevention strategies have been developed for settings where resources limit treatment for drowning victims.
- All significant drownings induce pulmonary injury and hypoxia by the amount of water aspirated and the duration of submersion.
- Pulmonary and neurologic support is essential to optimize the victim’s chance of a favorable outcome from this hypoxic event.
- Electroencephalography may be indicated in obtunded drowning victims to assess for subclinical seizures.
- No prognostic scale or clinical presentation accurately predicts long-term neurologic outcome; normal neurologic recovery is documented in patients with prolonged submersion, persistent coma, cardiovascular instability, and fixed and dilated pupils.
- Hyperventilation, steroids, dehydration, barbiturate coma, and neuromuscular blockade do not improve outcome after resuscitation.
- Comatose patients who have been resuscitated after reasonable submersion time regardless of rhythm should not be rewarmed above 34°C.

CHAPTER 137: QUESTIONS & ANSWERS

137.1. Which of the following is the greatest risk factor for death from drowning?
A. Ethanol
B. Male gender
C. Poor swimming ability
D. Saltwater drowning
E. Warm water

Answer: A. Ethanol is a major risk factor for drowning and for death from drowning. Ethanol is a contributing factor in up to 50% of drowning incidents among adolescents and adults. More males drown than females, but male gender alone does not increase the risk of death from drowning. No direct evidence exists relating swimming ability to risk of death from drowning. Although frequently cited in older literature, there is no significant difference between saltwater and freshwater drowning. Although case reports of good survival from cold-water drowning exist, overall mortality is greater in cold water than in warm water.

137.2. A 13-year-old boy is brought to the emergency department (ED) after an apparent drowning. Family and paramedics report the patient was submerged for approximately 4 minutes. Bystanders immediately began cardiopulmonary resuscitation (CPR) immediately. Paramedics intubated the patient and continued CPR, which has now been ongoing for 10 minutes. On arrival in the ED, the patient has a Glasgow Coma Score (GCS) of 3, unreactive pupils, no pulse, and is in asystole on the cardiac monitor. What is the most appropriate next step?
A. Cessation of treatment/pronounce death
B. External cardiac pacing
C. Induction of hypothermia
D. Intravenous epinephrine
E. Unsynchronized defibrillation

Answer: D. Although this patient will likely have a poor outcome, asystolic victims of drowning have a higher incidence of full neurologic recovery than patients with asystole from other causes. Poor prognostic indicators are age younger than 3 years old, submersion greater than 5 minutes, delay in initiation of CPR greater than 10 minutes, hypothermia, severe acidosis, unreactive pupils, GCS of 3, and asystole. The decision to cease care must be made on a case-by-case basis, but initial treatment of asystole should be begun in drowning victims following standard advanced cardiac life support (ACLS) protocols. Experiments with induction of hypothermia are ongoing in drowning victims, but the results are not definitive.

137.3. A 16-year-old boy presents with tachypnea and coughing. Family members state that they were swimming in a nearby lake when they noticed the patient with the previously mentioned symptoms. The patient is awake and alert but in obvious distress. He has a respiratory rate of 35 breaths per minute, with the remainder of his vital signs within normal limits. His oxygen saturation as measured by pulse oximetry is 84% while on high-flow oxygen. Pulmonary examination reveals diffuse rales. There is no evidence of trauma. In addition to intubation, which of the following is indicated?
A. Administer intravenous diuretics
B. Administer intravenous steroids
C. Obtain an electrocardiogram (ECG)
D. Perform maneuvers to remove fluid from the lungs
E. Place the patient in cervical spine precautions

Answer: C. Dysrhythmias are frequently associated with drowning, especially when no obvious cause is found. ECGs should be performed on all drowning patients. Antibiotics, steroids, and diuretics have all been studied in drowning victims, and none show any benefit. Cervical spine precautions are often initiated in all drowning victims but are not needed unless the patient has clinical signs of trauma or a history of motor vehicle crash, fall from height, or diving into the water. Maneuvers to remove fluid from the lungs (Heimlich, Patrick) are ineffective and potentially dangerous.

137.4. An 18-year-old man is brought to the emergency department (ED) after submersion in his swimming pool. Per witnesses, once the patient was brought from the water, he initially had severe coughing and complained of shortness of breath. On arrival to the ED, the patient denies shortness of breath and is not coughing. Vital signs as well as oxygen saturation are all within normal limits. Electrocardiogram (ECG) and chest radiographs are normal. What is the appropriate disposition of this patient?
A. Admission to telemetry for 23-hour observation
B. Admission to the general hospital for 23-hour observation
C. Admission to the intensive care unit for 23-hour observation
D. Discharge home after observation in the ED for 6 hours
E. Discharge home now

Answer: D. Any symptomatic patients or patients with a history of apnea, unconsciousness, or hypoxia should be admitted. Likewise, patients with dysrhythmias or abnormal chest radiographs should be admitted. Some effects of drowning can be delayed, so asymptomatic patients should be observed for 6 hours in the ED but can be safely discharged if they continue to be asymptomatic and can maintain normal room air oxygen saturation. They should be discharged in the care of a responsible family member or friend.
Radiation is energy that travels through space in the form of a particle or wave. It is produced by radioactive decay of an unstable atom (radionuclide or radioisotope) or by the interaction of a particle with matter. Particle radiation consists of particles that have mass and energy, and may carry an electric charge. Examples of particle radiation include alpha particles (helium nuclei), protons, beta particles (electrons ejected from the nucleus), and neutrons. Electromagnetic radiation consists of photons that have energy but no mass or charge. Radiation can be either ionizing or nonionizing depending on its energy and ability to penetrate matter. Electromagnetic radiation varies by frequency and wavelength as shown in Figure 138.1.

Radioactive decay (radioactivity) is the process by which a nucleus of an unstable atom loses energy by emitting ionizing radiation in the form of high-energy particles or rays. Radioactive decay can emit particles such as those described earlier or rays such as gamma or x-rays. Gamma and x-rays are high-energy photons that differ in their place of origin: gamma rays are emitted from the nucleus, whereas x-rays are produced as a result of changes in the positions of electrons orbiting the nucleus.

The type and rate of radioactive decay varies by radionuclide. The rate of decay is measured by the radioactive half-life (the time for half the radioactive nuclei in any sample to undergo radioactive decay) and varies from a few microseconds to billions of years. Radiation exposure can be external (eg, exposure to x-rays) or internal, resulting from the inhalation, ingestion, or injection of radioisotopes.

Radiation Measurements

The four different but interrelated units for measuring radiation (radioactivity, exposure, absorbed dose, and dose equivalent) are shown in Table 138.1. These units are also commonly expressed as fractions of whole units using the terms and abbreviations, (eg, milli [m] [1/1000th] and micro [μ] [1/1,000,000th]).

Radiation Protection

The principles of radiation protection include time, distance, shielding, and quantity. Reducing the time of radiation exposure will reduce the absorbed dose. The intensity of radiation is a function of distance from the source and follows the inverse square law: the intensity of radiation dose decreases inversely with the square of the distance. Shielding is the placement of an absorber (material that reduces radiation) between the person and the source. The effectiveness of shielding varies with the type of the radiation. For example, alpha particles can be stopped by a thin piece of paper or even the dead cells in the outer layer of the skin, whereas thick, dense shielding is necessary to protect against gamma rays. Limiting the quantity of radioactive material in the working area will also decrease exposure. National and international regulatory bodies set acceptable limits for occupational and population exposures to radiation.

Radiation Sources

Ionizing radiation and radioactive substances are natural and permanent features of the environment. The average annual radiation dose per person in the United States is 6.2 mSv (620 mrem). Fifty percent of this average dose comes from background radiation and 48% from medical procedures. The major sources of background radiation are radon and thoron (37%), cosmic radiation (5%), naturally occurring internal radioisotopes (eg, potassium-40 [5%]), and terrestrial background (3%). The major medical sources include computed tomography (CT; 24%), nuclear medicine (12%), interventional fluoroscopy (7%), and conventional radiography and fluoroscopy (5%). The remainder of the average annual radiation dose comes from occupational and consumer sources.

Radon is a naturally occurring radioactive gas that is formed from the radioactive decay of uranium. Radon can accumulate in homes and is the second leading cause of lung cancer in the United States. Radon exposure is estimated by measuring radon levels in the air using inexpensive and readily available kits. If indoor levels of radon are ≥4 pCi/L, then the US Environmental Protection Agency recommends that the homeowner consult a certified radon mitigation specialist to reduce radon air levels in the home.

Although radiation-related accidents are rare, the consequences of exposure or significant internal contamination can be fatal. The Radiation Emergency Assistance Center at Oak Ridge National Laboratory maintains a worldwide registry of serious radiation accidents. Between 1944 and 2012, there have been 454 radiation accidents recorded worldwide. The greatest numbers of serious accidents have occurred with sealed sources, which include brachytherapy sources used in radiation oncology and industrial radiography devices (n = 214), followed by x-ray devices (n = 86). Radioisotopes used in medical diagnosis and therapy have caused almost 11% percent of major radiation accidents.

Serious nuclear power accidents include the Fukushima Daiichi disaster (2011), the Chernobyl disaster (1986), Three Mile Island (1979), and the SL-1 accident (1961). The radioisotopes most commonly released from nuclear reactor accidents include iodine, cesium, and strontium. Chernobyl had the largest number of radiation-related injuries. About 150 individuals who received very high whole-body doses were treated for acute radiation sickness; 28 of these died within a relatively short time, and approximately 20 more have since died from radiation-related diseases. Radiation to the thyroid from radioisotopes of iodine released during Chernobyl accident has caused several thousand cases of thyroid cancer with children being the most susceptible population.

The detonation of nuclear bombs has the greatest potential to produce mass casualties. The acute and long-term effects have
been well documented following the bomb blasts in Hiroshima and Nagasaki in 1945 (18 and 22 kilotons). Today’s nuclear weapons are orders of magnitude more devastating. Another potential scenario is the detonation of a low-yield nuclear bomb by terrorists. A 10-kiloton nuclear detonation within a city in the United States would result in a zone of destruction of up to 2 miles from ground zero and would expose hundreds of thousands of people to radiation.8 A more likely terrorist scenario is the explosion of a dirty bomb. A dirty bomb is the combination of a conventional explosive with a radioisotope illegally obtained from medical or industrial sources. The radioisotopes most likely to be used in a dirty bomb are cesium-137, cobalt-60, or strontium-90.7 Although the acute radiation risks from a dirty bomb detonation are low, the localized residual radiation contamination would likely cause wide spread panic.

**Pathophysiology**

The biologic effects of radiation exposure are determined by the type of radiation, the total dose, the dose rate, the volume of tissue or anatomical body part irradiated, and individual susceptibility factors. The amount of energy released in matter (linear energy transfer) varies by type of radiation. Different types of radiation are assigned a quality factor (QF) based on their ability to produce biologic damage in exposed tissue. Gamma rays, x-rays, and beta particles have a QF of 1. Alpha particles (internal exposure only) have a QF of 20, whereas neutrons have a QF range of 3 to 20, depending on their energy.

**Ionizing radiation** includes particles and photons that have sufficient energy to produce ionization of the atoms that they encounter. Alpha particles, beta particles, and neutrons are examples of particle ionizing radiation. Only the high frequency portion of the electromagnetic radiation (gamma rays, x-rays, and far ultraviolet) has sufficient energy to produce ionization. Other frequencies and wavelengths (near ultraviolet, infrared, microwaves, radio waves, and very or extremely low frequency radiation) are nonionizing. The health effects of exposure to nonionizing radiation depend on the frequency and wavelength. For example, ultraviolet light can produce sunburns, visible light (eg, lasers) can produce corneal and retinal burns, and microwaves can produce heating of body tissues.

The effects of ionizing radiation on tissue can be direct or indirect. Direct effects include single- and double-strand DNA breaks. Indirect effects act through generation of free radicals that then attack other molecules in the cell. Cells vary in their sensitivity to radiation. In general, cells that are undifferentiated, divide quickly, and have high metabolic activity are most radiosensitive. Examples of these types of cells include bone marrow stem cells, lymphocytes, spermatogonia, intestinal crypt cells, and epidermal basal cells. The effects of radiation can be deterministic or stochastic. Deterministic effects are those in which the severity of injury is a function of dose (eg, bone marrow suppression). Stochastic or probabilistic effects are those in which the probability of an effect, rather than its severity, is a function of dose. An example of a stochastic effect is the development of radiation-induced cancer.

For external exposure, the site of the body that is irradiated (eg, bone marrow vs. upper extremity) is an important determinant of the resulting effects. For internal exposure, the biodisposition of the radioisotope, its radiologic and biologic half-lives, as well as the types of radioisotopes produced during radioactive decay are important determinants of the effects. The effective half-life reflects both the radiologic and biologic half-life and can be calculated as 1/effective half + 1/physical half-life.9 For example, iodine-131 has approximate biological half-life of 57 days and a radiologic half-life of 8 days. The resulting effective half-life is approximately 7 days. Biodisposition refers to the absorption, distribution, metabolism, and excretion of a radioisotope. Radioisotopes will have their greatest effects at the sites in the body where they are concentrated. For example, radioiodine concentrates in the thyroid gland and the resulting effects, such as thyroiditis or thyroid cancer, occur at the site of concentration.
Acute Radiation Syndrome (ARS) occurs after a patient is exposed to whole body radiation. ARS can result from external or internal exposure to radiation and varies in nature and severity by dose, dose rate, dose distribution, and individual susceptibility. This syndrome can result from external or internal exposure to radiation. The patterns of symptoms and signs of ARS overlap and the timing of the progression through the phases can be accelerated with increasing doses. There are three phases to ARS: prodromal, latent, and manifest illness.

In the prodromal phase, initial symptoms are typically nonspecific and include anorexia, nausea, vomiting, and fatigue. This phase is useful to help predict the severity of the radiation injury. The presence, onset, and frequency of nausea and vomiting, although nonspecific, can serve as a prognostic factor. Early onset of nausea and vomiting, the persistence of it, and the presence of diarrhea indicates a severe radiation injury.

The latent phase is a period of initial symptom improvement. Those with lethal radiation doses may not have a symptom free period and progress from the prodromal phase directly to the manifest illness phase.

The manifest illness phase has three sub-syndromes that may occur and overlap depending on the radiation dose received (Table 138.2). All organs are affected by radiation; however, the relative sensitivity of organ systems exposed to radiation determines the clinical symptoms. Tissues with greater rates of cellular division, particularly the hematopoietic and gastrointestinal systems, are most radiosensitive.

The hematopoietic sub-syndrome is the first sub-syndrome seen as the hematopoietic system is the most radiosensitive. This sub-syndrome can appear at doses greater than 1 Gy and typically results in bone marrow suppression. At doses less than 1 Gy (100 rem), most cells survive but may be susceptible to radiation-induced cancer. Lymphocyte depletion is the first cell line to decrease and with high doses of radiation the drop will occur sooner and with greater severity.

The gastrointestinal sub-syndrome begins to occur at doses nearing 6 Gy about 1 week after exposure. Patients will display nausea, vomiting, gastrointestinal bleeding, malabsorption, and massive fluid losses potentially leading to hypovolemia and cardiovascular collapse. These symptoms are due to death of the intestinal epithelial precursor cells and resultant denuding of the intestinal epithelial surface. Thrombocytopenia and immunosuppression from the accompanying hematopoietic sub-syndrome predisposes patients to infection and bleeding.

The neurovascular sub-syndrome results from doses greater than 10 Gy and is typically lethal. Patients will develop the following: irritability, altered mental status, seizures, prostration, ataxia, and hypotension. Coma and death usually occur within a few hours. Because of the high dose of radiation needed to produce these findings, patients often die before progressing to the latent phase.

Local Radiation Injury

Cutaneous involvement can occur following a radiation exposure. It can be one component of ARS with other organ involvement or it can occur alone. Radiation injury limited to the skin and the tissues located directly beneath the area of injury is termed a local radiation injury (LRI). This injury typically happens after a patient handles or has close contact with an industrial radioactive source. LRI can also result from medical testing or therapy, such as fluoroscopy, nuclear medicine studies, and CT scans. Inflammation, oxidative damage, and damage to the microvasculature are all involved in the pathophysiology of LRI. Hair loss occurs after exposure to 3 Gy, erythema is seen after exposure to 6 Gy, wet desquamation occurs after 15 Gy, and necrosis occurs after 20 to 25 Gy of localized skin exposure (Table 138.3).

**DIFFERENTIAL DIAGNOSES**

The initial signs and symptoms following radiation exposure are nonspecific and include anorexia, nausea, vomiting, and fatigue. In the absence of an exposure history, these symptoms in the prodromal phase of acute radiation sickness can be confused for gastroenteritis with its long list of differential diagnoses. Neutropenia seen after whole body radiation exposure also has many other etiologies, including viral infections, medications, certain autoimmune disorders, and nutritional deficiency.

The severe symptoms following high-dose radiation injury resulting in the neurovascular sub-syndrome can occur with any catastrophic cardiovascular or neurological event. Local radiation injury can appear similar to thermal burns but differ in their progression over time.

**DIAGNOSTIC TESTING**

If contamination with radioactive material is a possibility, then the patient should be surveyed with a contamination survey instrument (eg, Geiger Muller detector). These detectors are designed to measure the presence of radioactive material in counts per minute. There are a variety of other radiation detection devices that are used to measure field strength in units of mrem/hour or µSv/hour. These latter types of instruments are most often used to measure radiation fields at the event scene. The hospital radiation safety officer should be consulted to assist in performing radiation surveys of potentially contaminated patients or objects.

Quantifying the absorbed dose of radiation can be challenging, especially in the emergency department (ED). Information on the radiation source, field strength, time of exposure, distance, shielding, and routes of exposure is often incomplete. Although radiation doses can be reconstructed at a later time by health physicists, emergency clinicians will most often rely on biodosimetric tools, such as time to vomiting and lymphocyte depletion kinetics. These tools are available at www.remm.nlm.gov/ars_wbd.htm#vomit.

A baseline complete blood count (CBC) with differential and absolute lymphocyte count should be obtained and repeated every 6 hours for the first 24 hours and at least daily thereafter. The absolute lymphocyte count at 48 hours after exposure is a good predictor of radiation injury (Fig. 138.2). If the absolute lymphocyte count is greater than 1200 cells/µL, it is unlikely that the patient has received a clinically significant dose of radiation. If the absolute lymphocyte count falls between 100 and 500 cells/µL at 48 hours, a significant or even lethal dose of radiation should be suspected. A level in this range is an indication for neutropenic precautions. Weeks later, thrombocytopenia and anemia may develop because these cell lines are more radioresistant. Serum lipase, liver function tests, and C-reactive protein (CRP) should also be obtained and repeated at least daily. If the patient has been exposed to radioisotopes, rather than just external radiation, obtain nasal and mouth swabs and collect 24-hour urine and feces specimens for radiation bioassay. Hospital nuclear medicine departments may have equipment that can be adapted and used for the diagnosis of internal contamination (eg, thyroid scanners and gamma cameras).

**MANAGEMENT**

**Prehospital Care**

Information should be gathered regarding the exposure event: the numbers and types of patients potentially affected, the radionuclide involved, the route of exposure, and the estimated dose of radiation. Multiple triage guidelines exist to help guide transport and decontamination of individuals in the prehospital setting and are available to the public (Table 138.4). Most communities will have a disaster plan for radiation incidents, which should be activated if a significant number of patients are involved. Decontamination should be initiated at the scene. Patients with abnormal vitals should have partial decontamination, such as clothing removal, at the scene before expeditious transportation to an ED. Unstable patients should be rapidly transported in lieu of decontamination measures. Radio contact with the receiving hospital should be provided to facilitate preparations. If the community disaster plan has a designated hospital for radiation-contaminated victims, patients should be transported directly to that facility, bypassing hospitals less equipped to care for these complicated patients.

**Emergency Department**

**Preparation**

The chaos that occurs following radiation exposure incidents suggests that a community disaster plan should be developed with a predetermined individual empowered to make decisions about evacuation and other issues concerning the at-risk population. On notification of the numbers and types of patients involved in a radiation exposure accident, a decision should be made about implementation of a full disaster plan versus a limited response. The hospital radiation control officer, usually a radiologist, toxicologist or pathologist, should be contacted immediately. The radiation
control officer should monitor all patients and medical personnel with a radiation counter and should supervise the "cleanup" and the routing of patients to minimize "tracking," or spread, of contamination. Information dissemination to the public is critical. Timely and accurate information and instructions should be given to a public relations person for dissemination to the news media to minimize the chaos and paranoia that inevitably result from such incidents.

External Contamination

Radiation contamination is not an acute threat to the life of the patient or the provider, and its presence should not preclude institution of lifesaving measures. If standard precautions are taken, the risk to the health care providers is minimal. This was true for the physicians caring for Alexander Litvinenko, a former agent of the Federal Security Service of the Russian Federation who was poisoned with a radioactive substance. It was 3 weeks before it was determined what he was internally contaminated with polonium 210. Because the risk is minimal, care for life-threatening conditions and evaluation for severe traumatic injuries takes precedence over decontamination measures. A general approach to the patient exposed to radiation developed by the Radiation Emergency Assistance Center/Training Site of Oak Ridge Associates Universities is shown in Figure 138.3.

When a person is irradiated, such as in a patient who has just received a CT scan or x-ray, no hazard exists to medical personnel and the patient may be handled like any other emergency patient. If a patient is determined to be contaminated with radioactive material by survey with a radiation counter (such as, a Geiger counter), then they require decontamination. Universal precautions, including rubber gloves, shoe covers, and respirators if airborne contamination is suspected, are effective in protecting personnel and the work area from contamination. The only variation is to wear two sets of gloves and to change the outer pair when appropriate to avoid cross-contamination. The patient’s clothing should be removed and placed in plastic bags. Removing a patient’s clothing and shoes will remove about 90% of the radiation from the patient. If possible, soap and water cleansing of exposed skin should be performed. All materials, including wash water, should be placed in containers and labeled as radioactive waste. After decontamination, the patient should be surveyed again. Decontamination should be repeated until the patient’s radiation reading is only two times background radiation. If decontamination methods are causing damage to the skin, they should be discontinued regardless of the patient’s radiation survey results.

Wounds should be decontaminated with saline or water. High pressure irrigation is more important than the irrigation solution. Foreign bodies should be removed and safely set aside for further analysis. Repeat survey of the wound for radiation should be done, and repeat irrigation may be needed. If further attempts at decontamination do not result in a decreased amount of radiation in the wound, then the wound should be treated as medically appropriate with surgical closure if needed. Attempts to surgically decontaminate the wound should be avoided because this will cause more localized damage.

Internal Contamination

Assessing a patient for internal contamination can be difficult because most beta and alpha emitters will not be detectable with a handheld survey device. If a patient is externally contaminated, they have a higher risk of being internally contaminated. For internally contaminated patients, management should focus on decreasing absorption, enhancing elimination, and blocking distribution to target organs. Treatment directed at internal contamination by particular radionuclides can include potassium iodide for radioactive iodine exposures, bicarbonate for uranium, Prussian blue for cesium and DTPA for plutonium and transuranics (Table 138.5).

Acute Radiation Syndrome

Hematopoietic Sub-Syndrome. Colony-stimulating factors (cytokines) that induce bone marrow hematopoietic cells to proliferate may have substantial benefit, with little risk in victims predicted to have moderate or severe bone marrow failure. Cytokine therapy should be started for the following reasons: greater than 2 Gy dose, decrease in lymphocyte count, and if leukopenia is expected to last more than 7 days. It should be started within 24 hours of exposure and continued until the absolute lymphocyte count is above 1000 cells/μL. Bone marrow transplant should be considered for patients who continue to have

Neurovascular Sub-Syndrome. Patients who develop signs and symptoms consistent with this sub-syndrome within the first 24 hours should be provided comfort care, because they likely sustained a lethal dose of radiation.

Local Radiation Injury

Patients who sustained a LRI are managed in a manner similar to thermal burn patients. Treatment at a burn center is preferred for débridement and wound care. Eventual amputation may be necessary in patients who present with symptoms such as pain and prolonged leukopenia (2 to 3 weeks) in spite of cytokine treatment; however, the patients must not have other significant organ involvement. Prophylactic antibiotics should also be given in accordance with the Infectious Disease Society of America recommendations for neutropenia.

Gastrointestinal Sub-Syndrome. Treatment for the gastrointestinal sub-syndrome is largely supportive with antiemetics (preferably serotonin receptor antagonists), antidiarrheals, fluid resuscitation, antibiotics, and monitoring for signs of gastrointestinal perforation.

CHAPTER 138 Radiation Injuries

DISPOSITION
The disposition of the patient will depend in part on the scale of the event and the availability of medical resources. A mass casualty event may require disaster triage and resource rationing. Fortunately, large-scale radiation events are rare, and most radiation accidents have generated small numbers of patients requiring emergency or intensive care. The time of onset to vomiting can be useful in determining likelihood of survival. Patients who experience vomiting within 2 hours of exposure will require hospitalization and careful medical observation, because they are likely to have sustained life-threatening doses of radiation. Patients with severe burns and those requiring surgical management should be transferred to a burn unit, preferably within 72 hours from the time of radiation exposure.

ADDITIONAL RESOURCES
Many resources are available for both assistance in diagnosing and managing radiation injuries and for reporting of incidents. Table 138.4 lists resources that can help guide diagnosis and treatment of radiation emergencies and provide evidence-based information for those without formal radiation medicine expertise.

Psychological Consequences
The general public harbors a profound fear of radiation and its effects on the body. Radiation is one of the most dreaded components of a terrorist attack or industrial accident. People are fearful of the long-term effects of radiation exposure such as cancer and also the effects on children. This fear can lead to ostracizing people or things associated with the area of the event or disaster. Furthermore, those who develop ARS or other illnesses related to radiation may have significant fear and depression requiring psychological post-traumatic support. Moreover, both health care providers and communities as a whole are at risk. As a result, proper information dissemination to the public and incorporating behavioral health professionals into the disaster response is extremely important.

and erythema shortly after radiation exposure. Due to the chronic vascular injury and the potential for even minor trauma to the area to recapitulate the injury, the following are important in the treatment of LRI: topical corticosteroids, hyperbaric oxygen (HBO) therapy, pentoxifylline and vitamin E therapy, and appropriate wound care.23
Patients contaminated with radiation pose very little risk to health care providers when appropriate precautions and decontamination procedures are employed.

Decontamination should not delay or impede the stabilization of patients in radiation emergencies.

Tissues with greater rates of cellular division, particularly the hematopoietic and gastrointestinal systems, are most radiosensitive.

Vomiting and skin burns occurring shortly following radiation exposure are predictors of severe radiation injury.

The 48-hour absolute lymphocyte count is the most important prognostic indicator and should be drawn on suspected radiation exposure patients.

Most therapy is supportive and symptomatic except for exposures involving the ingestion or inhalation of radioactive material, when specific therapy with blocking or chelating agents may be indicated.

Formal consultation at the hospital, regional, and national levels is available 24 hours a day and should be used for assistance when any patient with radiation injuries is evaluated.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Patients who are exposed to external beam radiation are not made radioactive and are not a hazard to others. Decontamination and isolation are not necessary. With a normal physical examination and minimal symptoms, this patient can be followed as an outpatient. The most important action in this instance is to educate the patient.

138.3. What is the most important laboratory test to be performed 48 hours after exposure in determining the prognosis of a patient exposed to a significant radiation source?

A. Absolute lymphocyte count  
B. Absolute neutrophil count  
C. Karyotype  
D. Platelet count  
E. Serum albumin

Answer: A. Monitoring the kinetics of lymphocyte depletion during the first 48 hours following a radiation exposure is very useful at estimating the radiation dose received. The 48-hour absolute lymphocyte count is the most important prognostic indicator and should be drawn on all suspected radiation exposure patients. Levels greater than 1200/μL indicate a clinically insignificant dose of radiation and an excellent prognosis. Levels less than 500/μL indicate a significant and possible lethal exposure. None of the other answer choices carry prognostic significance.

138.4. What organ system is the first to show signs and symptoms following a significant radiation exposure?

A. Central nervous  
B. Dermatologic  
C. Gastrointestinal  
D. Genitourinary  
E. Hematopoietic

Answer: E. The radioisotopes most commonly released from nuclear reactor accidents include iodine, cesium, and strontium. Release of radioiodine from the Chernobyl reactor resulted in thousands of thyroid cancer cases among the exposed population.

REFERENCES

**Answer:** C. The first signs and symptoms of acute radiation injury are nausea and vomiting. An earlier onset of symptoms indicates more severe exposure. Typically, exposure to a radiation dose of at least 1 Gy is necessary to produce symptoms.

138.5. A 45-year-old man is accidently exposed to a radiation field of 850 mSv/hour for 4 hours while working on the clean-up of a nuclear power plant accident. Other than general supportive care, which of the following medications may improve his survival?

A. Acyclovir
B. Colony-stimulating factor (cytokines)
C. diethylenetriaminepentaacetate (DTPA)
D. Erythropoietin
E. Potassium iodide

**Answer:** B. This patient's radiation dose is sufficient to produce the hematopoietic component of acute radiation syndrome (ARS). Cytokines or colony-stimulating factors have shown modest effects in improving survival. Irradiated patients may develop oral herpes, and acyclovir can be used for treatment but does not affect survival. Anemia is present in most irradiated patients but is usually not clinically significant, and erythropoietin has no role. DTPA is a chelating agent that can be used for patients with internal exposure to plutonium or transuranics. Potassium iodine is useful if a patient is exposed to radioactive iodine, because it will compete with the radioactive iodine for uptake into the thyroid gland, resulting in overall less radioactive uptake.

138.6. What type of radiation event is most likely to cause incorporation and internal contamination?

A. A portable x-ray machine
B. Detonation of a dirty bomb
C. Fluoroscopy
D. Proton-beam radiotherapy
E. Solar flare

**Answer:** B. A dirty bomb is the combination of a conventional explosive with a radioisotope illegally obtained from medical or industrial sources. Dispersal of the radioisotope is likely to produce incorporation of the radioisotope through inhalation and inadvertent ingestion. The other radiation sources listed result in external radiation.
Approach to the Poisoned Patient

Timothy J. Meehan

**SECTION TWO**

Toxicology

**CHAPTER 139**

**PRINCIPLES OF TOXICITY**

Most poisoned patients seen in the emergency department (ED) are adults with intentional oral drug overdoses. Other common clinical scenarios include accidental poisoning in children, which represent the majority of calls to regional poison control centers.1 Illicit drugs of abuse; chronic poisoning from supratherapeutic pharmaceutical agents; environmental, industrial, and agricultural chemical exposures; envenomation; and medication interactions are other causes of toxicity. In the ED, it is important to evaluate and recognize scenarios where there may be immediate or delayed toxicity, as well as initiating decontamination, enhanced drug elimination, and administering more focused antidotal strategies, when indicated.

In regards to a specific patient with a particular ingestion, essential historical points include: the agent itself, the route of exposure, the amount ingested, possible co-ingestants, and the timing of the exposure. Knowing these facts can help make a determination regarding the expected course of care in the ED and help to mobilize resources.

**CLINICAL FEATURES**

**Toxicologic History and Physical**

Oftentimes, the poisoned patient may be altered or obtunded, or uncooperative with the examiner. This leaves the history limited to that which can be gleaned from witnesses, such as paramedics or family, and the information generated from the physical examination restricted to those functions over which the patient does not have conscious control.

Historical information must be pulled from all available sources.2 A family member or friend may offer insight into the circumstances behind the patient's exposure, (eg, intentional or accidental). Information regarding what medications or substances were available to the patient, and the timing of ingestion also is important. Paramedics routinely will bring in all medication bottles present at the scene—not just the patient’s prescribed medications or alleged ingestion. A patient attempting suicide may intentionally mislead the ED staff, or medications may have been stored in mislabeled containers. Other sources of potentially useful information include state controlled-substance registries, pharmacy records, and previous medical records. Accessing the patient’s text-messaging history also may be helpful, if the patient or guardian consents to this.

For chemical exposures in either the home or workplace, avoid exposure to other individuals in the ED. Proper identification of the substance is important to initiate care and obtain product safety information, such as a Material Safety Data Sheet. Consequently, one could consider taking a picture of the label including any precise chemical numbers; if a substance is brought to the ED, then take appropriate steps to avoid further exposure, such as sealing in an airtight container.3,4

Poisoned patients are frequently unwilling or unable to participate in an interactive physical examination. The toxicologic physical examination, therefore, rests upon observing factors that do not require cooperation to elicit. Many ingestants can cause derangement of the pulse and respiratory rates, as well as blood pressure.2 Thus, rapid and accurate recording of the patient’s vital signs, including a rectal core temperature and pulse oximetry, should be done and repeated at appropriate intervals. The overall level of consciousness, pupillary size, and presence or absence of seizure activity may suggest a particular agent (Boxes 139.1 and 139.2). Examination of the skin and mucous membranes with particular attention toward discoloration and level of moisture may suggest poisoning by any of several agents (Box 139.3); it may also reveal evidence of injection drug abuse, such as “track marks” or ulcerations from “skin popping.”5 A careful neurologic examination focusing on the level of muscle tone, clonus, or hyperreflexia can assist in the diagnosis of serotonin syndrome or neuroleptic malignant syndrome (NMS).6 Finally, certain intoxicants may have particular odors associated with them; the presence of such an odor ought alert the clinician to the possibility of poisoning by one of these agents (Table 139.1). However, the absence of a characteristic smell is not accurate in excluding poisoning.

**Toxidromes**

Toxidromes are constellations of signs and symptoms based on autonomic and neurochemical processes that can suggest a particular class of exposure and direct management and therapy.7 The five traditionally described entities include the sympathomimetic, anticholinergic, cholinergic, sedative/hypnotic, and opioid toxidromes. In addition, serotonin syndrome and NMS have been well described.

**Sympathomimetic**

This toxidrome is defined by a state of sympathomimetic excess, typically causing those effects expected from the “fight or flight” reaction. Patients are often altered and may be delusional—especially with ingestion of substituted amphetamines, such as N-methyl-3,4-methylenedioxyamphetamine (MDMA).7 Their vital signs are typically elevated, and present with hypertension, tachycardia, and tachypnea. They may also be hyperthermic as a consequence of an increased metabolic rate. Mydriasis and diaphoresis may also be present. In severe overdoses, derangement of
cardiac output can occur—decreased diastolic filling time coupled with arrhythmogenesis—resulting in circulatory collapse and shock, which may be refractory to fluid resuscitation and pressor agents.

**Anticholinergic**

Many pharmaceuticals have antimuscarinic properties, and thus this toxidrome is commonly encountered. By blocking normal cholinergic tone, an alteration in the normal homeostatic balance between the sympathetic and parasympathetic arms of the autonomic nervous system occurs. This allows the sympathetic side to function unopposed and generates a state of relative sympathomimesis. Therefore, many of the symptoms attributable to the anticholinergic toxidrome—delirium, hyperthermia, mydriasis, and cutaneous flushing—share similarity. In contrast, as the secretory glands of the skin and mucous membranes are cholinergically innervated, these systems are typically dry and not diaphoretic as found in the sympathomimetic toxidrome. The typical signs and symptoms can be recalled by the mnemonic “mad as a hatter, hot as a hare, blind as a bat, red as a beet, and dry as a bone.”

**Cholinergic**

The cholinergic toxidrome results from overstimulation of the parasympathetic portion of the autonomic nervous system, which

Chapter 139  Approach to the Poisoned Patient

Opioid

Similar to sedative/hypnotics, the opioid toxidrome also involves sedation and a diminished respiratory drive. With the notable exception of pentazocine and propoxyphene, this toxidrome causes pupillary miosis. The diagnosis is confirmed by noting a response to naloxone, a direct opioid receptor antagonist. However, because certain opioids have higher potencies, a lack of response does not exclude opioid intoxication. Furthermore, this is a clinical diagnosis because not all opioids will be detectable by the standard drug screen (discussed later).

Serotonin Syndrome

A state of serotonergic excess defines this toxidrome, and it is often precipitated by the addition of a new serotonergic agent or a substance that interferes with the metabolism of a previously tolerated agent. Typically described with selective serotonin reuptake inhibitors (SSRIs) and monoamine oxidase inhibitors (MAOIs), it has been reported with cyclic antidepressants and atypical antipsychotics. Consequently, serotonin syndrome typically occurs within hours to days of introduction to a new medication; although it has been described in a delayed fashion due to the prolonged half-lives of some antidepressants. The manifestations of serotonin syndrome include altered mental status, hyperthermia, and agitation; as well as hyperreflexia, clonus, and diaphoresis.

Neuroleptic Malignant Syndrome

Similar to serotonin syndrome, NMS also presents with altered mental status, hyperthermia, and agitation; however, unlike serotonin syndrome, peripheral muscular effects tend toward maintaining the “rest and digest” functions. These patients typically have “fluids coming from every orifice” as a consequence of increased glandular secretion, and present with diaphoresis, urination, miosis, bronchorrhea, emesis, lacrimation, lethargy, and salivation (Box 139.4). Agents of concern are primarily anticholinesterase agents, such as organophosphates and carbamate insecticides. These substances are readily available as pesticides; but they have also been engineered as weapons of mass destruction, typically referred to as nerve gases. It is important to rapidly recognize this toxidrome because patients frequently die from excessive bronchorrhea, effectively drowning in their own secretions, unless timely antidotal therapy and cholinesterase regenerators can be given.

Nicotine poisoning from tobacco can occur in children who ingest detritus, such as used cigarettes or chewing tobacco, as well as liquids from electronic cigarettes. Given the role of nicotine in both the central and peripheral autonomic nervous systems, the clinical picture in these poisonings may resemble both sympathomimetic and cholinergic toxidromes as noted in Box 139.4.

Sedative/Hypnotic

The hallmark of this toxidrome is sedation. This typically occurs on a spectrum depending on the particular ingestant, route, and potency. In severe ingestions, a state of general anesthesia may be reached with loss of tone and airway protective reflexes. In addition, it may cause hypothermia through suppression of muscle metabolism. It is well known in the ED, because ethanol intoxication is frequently seen. Other agents such as barbiturates and benzodiazepines will also cause a similar picture, as will illicit substances such as gamma-hydroxybutyrate (GHB). The coincidence of traumatic injuries may be high, and one should have a low threshold for evaluating to exclude their presence.

Nicotine poisoning from tobacco can occur in children who ingest detritus, such as used cigarettes or chewing tobacco, as well as liquids from electronic cigarettes. Given the role of nicotine in both the central and peripheral autonomic nervous systems, the clinical picture in these poisonings may resemble both sympathomimetic and cholinergic toxidromes as noted in Box 139.4.
The thorough physical examination may also reveal findings that could suggest specific intoxicants, as noted in Box 139.6. The most important diagnostic approach is maintaining a broad differential diagnosis of both toxicologic and non-toxicologic causes for the patient’s presentation, and avoiding premature conclusion. The differential diagnosis may be extremely broad, particularly when ingestion of a toxin is not known, or felt unlikely, or much more specific, when a certain agent, or class of agent is known to be involved.

**DIAGNOSTIC TESTING**

Diagnostic testing is guided by the clinical findings and suspected toxin(s) involved. When a patient presents with altered mental status and hyperthermia, testing may focus on differentiating a toxic cause from thyrotoxicosis or acute infectious disease. Patients with intoxication and evidence of trauma may require evaluation for head trauma as a cause of their altered mental status. In most instances, however, it is known that the patient has a potentially toxic exposure and some or all of the involved toxins have been implicated or identified. The approaches to individual toxins and syndromes are outlined in the relevant chapters. In the setting of an unknown overdose or exposure, a broad array of laboratory testing is often used to screen for abnormalities and potentially elucidate the clinical picture. The diagnostic studies routinely checked are: complete blood count, serum chemistry with renal function, liver function tests, urinalysis (with a pregnancy test if appropriate), urine toxicology screen, serum alcohol concentration, serum lactate, and a bedside glucose. 11 Based on these results, or when the ingestion is known, other tests such as specific serum concentrations may be obtained; Box 139.7 lists those drug levels commonly available in most hospitals. When assays for a particular agent are not available, or are not

performed on site, empirical treatment generally begins before these results are available.

If the blood gas shows the presence of a metabolic acidosis, calculating the anion gap can further refine the possible etiologies.

The calculation is: $[\text{Na}] - ([\text{HCO}_3^-] + [\text{Cl}])$. The normal range is 8 to 12 mEq/L.

Metabolic acidosis without an anion gap typically results from loss of bicarbonate (diarrhea, renal tubular acidosis) or gain of chloride-containing compounds (ammonia, calcium chloride). Metabolic acidosis associated with an anion gap results from an increase in unmeasured serum anions and suggests several specific toxins and disease states (Box 139.8).

When ingestion of a toxic alcohol (such as, methanol, ethylene glycol, or isopropanol) is suspected, calculating the osmole gap may be helpful; because early in the poisoning course the patient may be minimally or non-acidemic. Furthermore, urine fluorescence is not sufficiently sensitive to be reliable and its absence cannot be used to “rule out” said ingestion. The osmole gap is discussed in Chapter 141.

Toxicology “screens” may also be helpful in diagnosing an unknown ingestion, provided that the limitations of these panels are understood. Blood toxicology screens can be falsely negative if the ingested drug has a short half-life and the sample is not drawn soon enough after the exposure. Urine toxicology screens are more reliable, because they typically have a longer time period for positive detection, typically 24 to 72 hours. Urine toxicology screens typically include phenylcyclidine (PCP), cocaine, opioids, amphetamines, and cannabinoids; however, these can vary among institutions, so knowing what is available in one’s facility is important in interpreting a positive or negative screen. The urine screen is also a qualitative, not a quantitative test; as such, a positive result does not necessarily imply acute toxicity. A urine toxicology screen can be falsely positive due to cross-reactivity between agents (such as, a “positive” PCP screen in the setting of dextromethorphan ingestion). Alternatively, urine screens can be falsely negative if the substance ingested does not cross-react with the tested analyte—such as, the case with methadone, which will not cross react with the opioid component of the urine toxicology screen (Table 139.2). Ultimately, the diagnosis of intoxication is clinical; urinary drug screening may be confirmatory but should not supplant clinical evaluation and judgment.

In addition to the blood work discussed earlier, one should obtain an electrocardiogram (ECG) if the patient is tachycardic or bradycardic, or may have ingested a cardiotoxic agent that can prolong the QRS or QT intervals, such as cyclic antidepressants and antipsychotic agents. Table 139.3 provides guidance regarding for which patients an ECG should be obtained.

**MANAGEMENT**

The general management of a poisoned patient involves providing appropriate supportive care, undergoing decontamination or enhancing elimination if indicated, and providing specific antidotal therapy where an antidote exists and is indicated. Specific strategies will be discussed at length in the following chapters regarding specific poisons. However, the basic framework remains the same.

Antidotes do not exist for every potential poisoning, and thus supportive care is the cornerstone of managing the poisoned patient. Following the basic “ABCs” of resuscitation by ensuring airway protection and adequacy of ventilation while maintaining the circulatory status of the patient with fluid resuscitation and vasopressor support is the prime focus. If the airway is compromised or in danger of becoming so, or if the respiratory effort is insufficient to maintain appropriate ventilation, intubation is usually the preferred course (with special care in the situation of a salicylate poisoning, which is discussed in Chapter 144).

Vascular access needs to be obtained, with peripheral and central venous catheters well-known to practitioners. Intraosseous lines are also viable access points from the toxicologic perspective, because there are no known contraindications to antidotal therapy through this route.

Once supportive care has been initiated and the immediate threat to the ABCs has been stabilized, one should then progress to a systematic assessment of decontamination strategies, enhanced elimination, focused therapy (antidotes), and getting help (consultation).

**Decontamination**

Decontamination is the process of preventing systemic absorption into the body. In the case of ocular or dermal exposure, this is achieved by copious irrigation with water, after removal of contaminated clothing to expose the area. Water irrigation is not used for metallic potassium, magnesium, or sodium (such as, found in “tracer” ammunition), because these can ignite on contact with water. Instead, in these very rare exposures, the area should be covered with petroleum jelly or mineral oil.

SYRUP OF IPECAC

Inducing emesis with syrup of ipecac is not indicated in the care of any poisoned patient in the ED. Syrup of ipecac use is associated with significant side effects (e.g., dehydration due to intractable vomiting) and complications (e.g., aspiration pneumonitis, Mallory-Weiss tears, and gastric rupture). There are also insufficient data and evidence showing improvement in clinical outcomes.13

GASTRIC LAVAGE

Gastric lavage, the process of directly removing an ingested substance from the stomach using a 30 Fr or larger orogastric tube, also has little data or evidence showing its efficacy and should not be performed routinely for the treatment of poisoned patients. Given the risks of aspiration and esophageal trauma, the American Association of Poison Centers suggests it only be employed...
“within an hour of ingestion of a potentially life-threatening poison which does not adsorb to activated charcoal or for which no antidote exists” and, even then, in a center with “sufficient expertise” to perform the procedure safely.13 Only a rare overdose will meet all these criteria; and hence, despite its once widespread use, gastric lavage is mostly of historical interest only.

**SINGLE-DOSE ACTIVATED CHARCOAL**

Historically, single-dose activated charcoal (SDAC) has been the mainstay of gastric decontamination in medical toxicology.14 Activated charcoal is a carbonaceous substance that has been exposed to high heat and steam, resulting in a large surface area to volume ratio, to provide ample surface space for ingested substances to adsorb, and thus decrease absorption into the body. Our current understanding of the role of activated charcoal in poison management is based on pharmaco-toxicologic data (lethality, availability of antidotes, or alternative detoxification therapies); pharmacokinetics (area under the concentration versus time curve in controlled volunteer studies); clinical trials in patients with overdose; and collective, empirical clinical experience.15-21 Studies involving healthy volunteers ingesting small (safe) doses of various agents do not accurately replicate the overdose (large ingestion) situation, so are of limited value. In addition, there are very few appropriately designed clinical studies assessing the benefit from SDAC. Therefore, due to the lack of convincing evidence demonstrating benefit in clinical outcome in human overdose, we do not recommend the routine use of activated charcoal following ingestion.13 We do, however, recommend its use in certain overdose scenarios.

Although few studies have shown a reduction of morbidity or mortality attributable to activated charcoal administration, and there have been reports of pulmonary aspiration of activated charcoal with serious patient harm, these aspiration events have occurred in a minority of patients receiving activated charcoal; and activated charcoal, accordingly, is considered a low risk intervention.21 With certain toxic exposures, SDAC administration may be reasonable after a consideration of the risk versus benefit for the patient in the context of the quantity and toxicity of the ingested substance, the time elapsed between ingestion and treatment, and the availability of alternative antidotes or decontamination procedures (eg, hemodialysis). Benefits include decreasing primary absorption, or binding during enterohepatic recirculation of a potentially toxic xenobiotic. These benefits are more likely to occur if:

- The activated charcoal is administered within one hour post-ingestion, and
- The patient is alert, able, and willing to cooperate with administration, and anticipated to remain alert and protective of airway reflexes, and either
  - The substance ingested has high toxicity (eg, verapamil, colchicine), or is a toxic, sustained-release agent (eg, bupropion SR), or
  - There is evidence of a massive ingestion of a toxic agent (eg, salicylates)

If the patient is sedated, has an unprotected airway, or is unwilling to drink the charcoal suspension, administration is contraindicated. This may be particularly true for young children with limited ability to drink the slurry. Furthermore, one should not place a nasogastric tube solely to administer activated charcoal, because the risk of aspiration or direct instillation of activated charcoal into the lungs rises in these patients, thus tipping the risk-benefit ratio.

Considering all of this information, how does one decide whether activated charcoal is indicated in a specific overdose? First, the ingested drug must have a high potential for toxicity and lethality. These drugs are listed by class in Box 139.9. If the drug ingested has low toxicity (eg, ibuprofen, diazepam), or there is an effective antidote available (eg, N-acetylcysteine for acetaminophen, digoxin immune fab for digoxin), activated charcoal administration is not advised.20

Second, the ingestion must be recent. For most overdoses, this means that the activated charcoal is administered within 1 hour of ingestions. For certain overdoses (sustained-release products, anticholinergic agents, massive ingestions), either because of pharmacokinetics or the quantity ingested, activated charcoal may be given up to 2 hours after ingestion. Many patients arrive at the ED more than 2 hours after the ingestion, or ingest the drugs over a period of several hours, often with alcohol, and do not meet this time requirement. Third, the ingestion must be amenable to adsorption by activated charcoal. This eliminates rapidly absorbed toxins (eg, ethanol) and those agents listed in Box 139.10. Fourth, the patient must be alert and anticipated to remain alert and be willing to take the activated charcoal slurry voluntarily. An algorithm guiding the administration of activated charcoal is shown in Figure 139.1. We recommend consultation with a regional poison center or medical toxicologist if there is uncertainty regarding the indications for activated charcoal.

Activated charcoal historically has most often been given in a dose of 25 to 100 grams (10 to 25 grams or 0.5 to 1.0 gram/kilogram in young children), but we advise customizing the dose to the dose of the ingested agent by administering activated charcoal in a weight ratio of 10:1 (ratio of activated charcoal to drug).20

**WHOLE BOWEL IRRIGATION**

In certain ingestions such as extended-release preparations, illicit drug packets, or metals (eg, iron and lead), continuous wholebowel irrigation may be indicated. Whole bowel irrigation (WBI) is performed with a balanced polyethylene glycol solution that...
does not participate in fluid exchange nor become absorbed into the body. To be effective, it requires a rate of 2 liters per hour in an adult; consequently, this will require nasogastric tube placement. However, if a patient is critically ill, has hypoperfusion of the gut, or has obstruction of the bowel, WBI is contraindicated because there have been reports of worsened morbidity and mortality in these clinical settings.

**Enhanced Elimination**

Once a toxin has been absorbed into the body, it undergoes metabolism and elimination; typically via hepatic and renal pathways. Certain substances are amenable to enhancing these elimination pathways either ex vivo as is the case with hemodialysis and its related therapies, or in vivo as is the case with multiple-dose activated charcoal (MDAC) and urinary alkalinization.

Hemodialysis and its related therapies are best suited to remove poisons of low molecular weight, low protein binding, and high water solubility; examples include toxic alcohols, lithium, and salicylates, as listed in Box 139.11. All forms of extracorporeal removal have been studied and found to be efficacious; the selection of a specific type of elimination modality ought to be made based on patient-specific factors and early consultation with a nephrologist in conjunction with a toxicologist or poison control center.

**MULTIPLE-DOSE ACTIVATED CHARCOAL**

Unlike preventing absorption of a drug as is the case for SDAC, MDAC is intended also to facilitate removal of a toxin that has already been absorbed. MDAC decreases xenobiotic absorption and elimination half-life when large amounts of the toxin are ingested and dissolution is delayed (eg, concretions, bezoars, or extended release formulations). It also is believed to create a hemoperfusion substrate for the gut wall microcirculation to permit "gastrointestinal dialysis," which generates a concentration gradient into the stool or certain poisons, which are then be eliminated by defecation. In addition, certain drugs are excreted in the bile, then reabsorbed by the gut, only to be re-excreted in the bile, a process called enterohepatic circulation. MDAC also may interfere with reabsorption of these drugs by binding them during their transit of the gastrointestinal tract. Drugs with significant enterohepatic circulation are listed in Box 139.12. As with SDAC, MDAC administration may cause pulmonary aspiration and intestinal obstruction. Aspiration is best avoided by applying the same conditions for administration as for SDAC—ie, patient awake, alert, and cooperating and is anticipated to remain awake and alert. Obstruction is more difficult to predict and prevent, although avoidance in situations with delayed gut motility (eg, critical illness, opioid or anticholinergic effects) is recommended to reduce this risk.

When MDAC is indicated, the initial loading dose of an activated charcoal–to-xenobiotic ratio of 10:1, is followed by
subsequent doses of 50% of the initial dose every 4 to 6 hours for up to 24 hours. MDAC may be discontinued when the patient’s measureable serum levels are no longer considered in the toxic range.

**SERUM ALKALINIZATION**

Certain water-soluble ingestants such as salicylates, methotrexate, and phenobarbital will undergo ion-trapping and enhanced urinary elimination if the serum is suffi ciently alkalized. This is especially important with salicylate poisonings, because alkalization not only promotes elimination but also prevents salicylate crossing the blood-brain barrier into the central nervous system (CNS). Monitor the serum pH and bicarbonate level, as well as the urinary pH, with the goal being a serum pH of approximately 7.5 and a urinary pH of approximately 8.0. Also ensure that the serum potassium level is normal, because alkalization will cause an intracellular shift of potassium and consequently increase urine reabsorption of potassium by excreting hydrogen ions into the urine; this will eliminate the pH gradient and dissipate the benefits of this process. To accomplish this, combine 150 mEq (3 amps) of 8.4% sodium bicarbonate into a liter of dextrose 5% in water (D5W) and add potassium (20 to 40 mEq total) to the intravenous fluid as well, with a rate not to exceed 250 cc/hour.

**INTRAVENOUS FAT EMULSION (INTRALIPID)**

Intravenous fat emulsion (IFE) is a newly introduced therapy for poison-induced cardiogenic shock. This therapy was first described for treatment of toxicity from local anesthetics, such as bupivacaine. IFE is proposed to work primarily by two separate mechanisms: (1) the lipid sink and (2) enhanced cardiac metabolism.27 The lipid sink theory posits that fat-soluble drugs are soaked up and removed from the site of toxicity, effectively increasing the volume of distribution for a fat-soluble drug. This is the predominant theory behind the use of IFE. A second theory involves optimization of cardiac metabolism. The heart under physiologic circumstances prefers free fatty acids; in times of stress, it switches to glucose metabolism for energy. A dose of IFE theoretically provides a large supply of free fatty acids to optimize energy use in the heart. In addition to providing supplemental energy for myocytes, IFE may also enhance activation of cardiac calcium channels.

Indications for IFE are not universally agreed upon. In addition to anesthetic agents, successful resuscitations have been described with refractory B-blocker overdose, calcium channel blockers, cyclic antidepressants, and bupropion and cocaine toxicity. Although originally described as a treatment for overdose patients in cardiac arrest, several reports now exist describing the successful use of IFE in critically ill patients prior to an arrest state with a pulse. Dosing for IFE also varies in the literature. If indicated, we recommend an initial bolus of 1.5 mL/kg of 20% lipid solution given over 2 to 3 minutes is most commonly recommended, followed by an infusion of 0.25 mL/kg/min. IFE should be used only in consultation with a medical toxicologist or poison center.

Despite recent enthusiasm for IFE, its use has associated complications, including extreme lipemia resulting in lab interference with blood tests (complete blood counts, chemistries, and coagulations studies), as well as acute pancreatitis, and acute respiratory distress syndrome.28

**Focused Therapy**

Although the majority of poisonings require supportive care alone, in selected ingestions specific antidotal therapy may be available. Evidence and experience support the use of several antidotes, which should be available either immediately (eg, stocked) or in a rapid fashion (eg, transported within a few hours). These antidotes and their indications can be found in Table 139.4, and their use is discussed in the relevant chapters.29,30

**Toxicology Consultation**

Most poisoning cases are straightforward and are easily handled by the emergency clinician. When the poisoning is severe, high risk, involves unfamiliar or multiple toxins, or occurs in a patient with significant comorbidity, we recommend consultation with a Poison Control Center or, if available, a medical toxicologist. Consultation can assist the bedside clinician in the determination of an unknown ingestion, critical management decisions, or whether an antidote or invasive procedure, such as hemodialysis, is advisable.

In the United States, a national toll-free phone number has been set up that will route a practitioner to their nearest Poison Control Center. This number is 1-800-222-1222.1

**DISPOSITION**

Patients with severe toxicity (such as, seizures, persistent cardiovascular instability, airway compromise, or significant metabolic derangements) should be admitted to an intensive care setting. Patients who are asymptomatic on arrival but have ingested a potentially dangerous substance or an extended-release preparation that could cause significant deterioration in their clinical status, are admitted to either an inpatient setting or an observation unit for 24 hours, or until peak toxicity has obviously passed

and the patient is physiologically normal or near normal. For patients who are asymptomatic after an ingestion of a minimally toxic substance and for whom other ingestions and psychiatric issues have been addressed, discharge after the ED visit, which typically takes at least 4 to 6 hours, is appropriate.

If the motivation behind the ingestion was suicidality, or self-harm, a psychiatric consultation is warranted. If a suicidal patient is to be admitted medically for observation, it is important to ensure that a sitter or other type of secure environment is available to prevent any further patient inflicted self-injury.

Key Concepts

- Toxidromes are constellations of signs and symptoms based primarily on vital signs and neuropsychiatric functions that are characteristic manifestations of certain toxic exposures. Recognition of the presence of a toxidrome can suggest a potential intoxicant and guide early interventions and management strategies. Examples of toxidromes include sympathomimetic, antimuscarinic, cholinergic, sedative-hypnotic, and opioid categories.

- Qualitative urine drug are inferior to quantitative serum levels in terms of guiding specific therapy.

- Syrup of ipecac is not indicated in the ED care of a poisoned patient. Gastric lavage is not part of routine care. When given in a timely fashion (1 hour post ingestion), activated charcoal may be indicated for potentially lethal agents in alert, cooperative patients as noted in Figure 139.1. Whole-bowel irrigation is rarely useful for management of poisoned patients but is potentially helpful for specific poisonings, such as metals, illicit drug packets, or sustained-release medications.

- Serum alkalinization enhances urinary drug elimination for certain drugs and is indicated for significant poisoning caused by salicylates, phenobarbital, and methotrexate.

- Hemodialysis is best suited to remove poisons of low molecular weight, low protein binding, and high water solubility; examples include methanol, ethylene glycol, lithium, and salicylates.

- Regional Poison Control Centers 1-800-222-1222 or a medical toxicologist can assist with antidotal therapy and may help facilitate patient disposition.

- If the motivation behind the toxic exposure was self-harm, a psychiatric consultation is warranted.

CHAPTER 139: APPROACH TO THE POISONED PATIENT

139.1. A 23-year-old man presents with confusion. His vital signs are blood pressure 105/77 mm Hg, heart rate 69 beats per minute, respiratory rate 10 breaths per minute, temperature 37.0°C, and arterial oxygen saturation (SaO2) 96% on 2 L NC. His eyes open only to pain, he localizes to pain, but he does not follow commands and his speech is confused. Otherwise, his physical examination is normal. After intravenous (IV) access is obtained and he is placed on continuous cardiac monitoring, what is the most appropriate next step?
A. Check arterial blood gases (ABG).
B. Check bedside serum glucose.
C. Give 50% dextrose 1 amp IV.
D. Give naloxone 2 mg IV.
E. Perform electrocardiogram (ECG).

Answer: B. All patients with altered mental status should have a rapid determination of their glucose. Although this patient has several abnormal vital signs, none necessitate immediate action. His Glasgow Coma Score (GCS) is 11, and it appears that his respiratory status is adequate. Dextrose should not be given unless hypoglycemia is documented. Naloxone is an opioid antagonist, and it could reverse the patient’s confusion if it is caused by opioids. This drug could be considered once other more easily reversible causes of confusion (eg, hypoglycemia) have been ruled out. ABG and ECG are both occasionally needed in patients with altered mental status, but neither is as urgent as glucose testing.

139.2. The odor on a poisoned patient can provide clues as to the substance causing the poisoning. If a patient smells of garlic, what should you be concerned about?
A. Cyanide
B. Hydrogen sulfide
C. Methyl salicylate
D. Organophosphates
E. Toluene

Answer: D. Arsenic, dimethyl sulfoxide (DMSO), yellow phosphorus, selenium, and tellurium can also have a garlic odor. Odors associated with the other answer choices are as follows: cyanide, bitter almonds; hydrogen sulfide, rotten eggs; methyl salicylate, wintergreen; and toluene, glue. Odors can aid in making the diagnosis but should not be relied on as completely diagnostic. Also, the lack of odors cannot be used to rule out a poisoning resulting from that substance.

139.3. A 17-year-old girl presents with delirium, tachycardia, dry skin, flushed face, decreased bowel sounds, dilated pupils, and urinary retention. A friend states that the patient had recently ingested some unknown medications in a suicide attempt. Which of the following medications is most likely responsible for the constellation of signs?
A. Alprazolam
B. Clonidine
C. Diphenhydramine
D. Hydrocodone
E. Pseudoephedrine

Answer: C. The patient is expressing the signs of classic antimuscarinic poisoning. Central nervous system (CNS) effects include the delirium and typical “picking movements” of the fingers. Suppression of the cholinergic system results in tachycardia. All secretory functions are inhibited, causing the dry, flushed skin, decreased bowel sounds, and urinary retention. Unopposed sympathetic activity results in dilated pupils. Alprazolam, clonidine, and hydrocodone can all cause the sedative toxidrome.
Pseudoephedrine can lead to the sympathomimetic toxidrome, which typically has diaphoretic skin but can otherwise appear similar to an anticholinergic presentation.

139.4. What is the elimination half-life of naloxone?
A. 30 minutes
B. 1 hour
C. 2 hours
D. 4 hours
E. 6 hours

**Answer: B.** The exact elimination half-life of naloxone is closer to 1.1 hours (1 hour 6 minutes). This is markedly shorter than the half-life of almost all opioids. For comparison, morphine has a half-life of approximately 2 hours, hydrocodone has a half-life of approximately 4 hours, and methadone has a half-life up to 30 hours. This means that repeat dosing of naloxone is often necessary when treating opioid overdose. A drug similar in action to naloxone, nalmefene, has a half-life of 10 hours and may sometimes be useful.

139.5. You suspect a patient has a cholinergic syndrome. Which of the following, if found, would make you question your diagnosis?
A. Confusion
B. Diaphoresis
C. Diarrhea
D. Fasciculations
E. Mydriasis (dilated pupils)

**Answer: E.** The typical cholinergic patient is “wet.” A common mnemonic used to remember the symptoms is SLUDGE—salivation, lacrimation, urination, defecation, gastrointestinal cramping, and emesis. Confusion can be present but is nonspecific. Frequently, cholinergic syndrome is caused by organophosphate poisoning, so fasciculations are common. Another common sign is miosis, not mydriasis.

139.6. Gastric decontamination with activated charcoal can decrease the absorption of certain toxins. However, before charcoal can be given, it must be determined that the risk of aspiration is low, the likelihood of reduction of toxicity or improved patient outcome is high, and that the ingestion occurred recently (within approximately 1 hour). Also, it must be determined that the substance ingested is actually adsorbed by charcoal. Which of the following substances is adsorbed by charcoal?
A. Gasoline
B. Hydrofluoric acid
C. Iron
D. Methanol
E. Metoprolol

**Answer: E.** Charcoal does not adsorb hydrocarbons (ie, gasoline), ionic substances (ie, strong acids or bases), metals (ie, iron), or alcohols. It does adsorb most therapeutic drugs with potential major toxicity, such as beta-blockers, calcium channel blockers, and cyclic antidepressants.

139.7. A 6-year-old boy is found playing with liquid pesticide by family members. The family states that he was drinking the solution. Paramedics find the child sitting in a puddle of liquid that smells strongly of pesticide. He is acting normally. En route to the hospital, the paramedics report that the child is now sleepier than previously but still easily aroused with a loud voice. His vital signs are within normal limits. They ask what they should do next. What do you advise?
A. Administer IV atropine
B. Administer oral activated charcoal
C. Administer naloxone
D. Perform rapid sequence intubation
E. Remove the child’s clothing and wash the skin

**Answer: E.** This child’s clothing has been impregnated with poison, and as long as the child is clothed, he will continue to absorb the poison. Ideally, all patients should be decontaminated on scene to expedite decontamination as well as to minimize the risk of contaminating others. Although this child may have ingested some poison, it is likely that far more is being absorbed from his skin than through his gastrointestinal tract. In addition, charcoal can cause complications, whereas removal of contaminated clothing is relatively safe. Although this child may eventually require intubation, he does not need it now. Most pesticides are organophosphates, so this patient may require atropine, but removal from the poison (taking off his clothing) will provide the greater immediate impact on his condition.

139.8. A patient suffering from serotonin syndrome will experience myriad physiologic abnormalities, including altered mental status, fever, agitation, tremor, and myoclonus. Many of the symptoms are nonspecific. Which of the following diagnoses is often mistaken for serotonin syndrome?
A. Anticholinergic syndrome
B. Brown recluse envenomation
C. Opioid withdrawal
D. Sepsis
E. Sympathomimetic overdose

**Answer: E.** Serotonin syndrome is characterized by altered mental status, fever, agitation, tremor, myoclonus, hyperreflexia, ataxia, incoordination, diaphoresis, shivering, and diarrhea. Similar symptoms are seen with overdoses of sympathomimetics, lithium, and monoamine oxidase inhibitors (MAOIs). Similar symptoms are also seen with neuroleptic malignant syndrome (NMS) and malignant hyperthermia. The antimuscarinic syndrome will give a “dry” patient without diaphoresis. Brown recluse envenomation produces local pain and possibly skin necrosis, as well as systemic symptoms of fever, nausea, and vomiting. Opioid withdrawal produces similar symptoms and will cause myalgias but without other musculoskeletal effects. Sepsis likewise can produce many of the systemic signs and symptoms seen in serotonin syndrome but without the musculoskeletal effects.
PRINCIPLES OF TOXICITY

The use and abuse of psychoactive substances are global and timeless. People used hallucinogenic plants to achieve altered states of consciousness in prehistoric times, and psychoactive substances have been used in all eras and cultures. As Osler remarked, “The desire to take medicine is, perhaps, the great feature which distinguishes man from other animals.” The human cost of substance abuse is high, and deaths secondary to the use of psychoactive substances are common. In the United States, illicit drug use results in thousands of deaths each year (Box 140.1).1

A major barrier to appropriate recognition and treatment of substance abuse is the lack of a precise definition. The American Psychiatric Association defines it as a maladaptive pattern of drug use associated with some manifest harm to the user or others. Physicians have a difficult time recognizing such abuse, particularly in patients with chronic pain syndromes. Chronic pain may not manifest the typical overt sympathetic changes or physical findings of acute pain. Patients may seek treatment because of perceived failure of their outpatient regimen, an acute flare up, or because of abuse or addiction. Therefore, emergency clinicians constantly walk a tightrope between undertreating legitimate pain and inappropriately rewarding substance abusers with controlled medications.

EPIDEMIOLOGY

A variety of stereotypes come to mind in compiling the profile of a substance abuser. Adherence to a belief in these stereotypes is a dangerous trap for the clinician. Physicians are likely to discount the possibility of drug intoxication in the well-dressed professional or in those at the extremes of age, but drug use and abuse spans the spectrum of society.

A large 2013 survey of teenagers in grades 9 to 12 found misuse and abuse of prescription medications to be the third most prevalent drug abuse behavior among teens, trailing only use of marijuana and alcohol. Abuse of over-the-counter (OTC) cough medications is on par with or higher than the abuse of illegal drugs, such as ecstasy and cocaine.2 Dextromethorphan abuse has become epidemic in the last decade. Increasing numbers of teens are ingesting dextromethorphan-containing OTC products, such as Coricidin HBP Cough & Cold tablets, known on the streets as “head shops,” and local suppliers. One prevalent example is known as bath salts. These products are available in small quantities, with packaging that usually includes the disclaimer “not for consumption” to avoid regulation. Bath salts contain synthetic cathinones, which are pharmacologically similar to methamphetamine and N-methyl-3,4-methylenedioxyamphetamine (MDMA) (ecstasy) and produce similar clinical effects.3 A variety of adverse effects have been reported from cathinone derivatives, including tachycardia, hypertension, agitation, hyponatremia, hallucinations, paranoia, and suicide.4,5 The legal status of these agents is in flux. The U.S. Department of Justice Drug Enforcement Administration has placed a number of the synthetic cathinones under Schedule I of the Controlled Substances Act; however, numerous other synthetic cathinones have been found in these products.

Elders also abuse substances, and geriatric patients may suffer new-onset psychosis as a result of sympathomimetic abuse or drug withdrawal. Drug use also occurs in pregnant women, resulting in both maternal and fetal morbidity. Manifestations of abuse may be acute, as in abruptio placentae or premature birth, or insidious, producing growth restriction and birth defects. Drug problems are more prevalent among lower socioeconomic groups, which are disproportionately affected by drug-related problems, such as incarceration, unemployment, acquired immunodeficiency syndrome, hepatitis, and tuberculosis.

The drugs of misuse or abuse most commonly involved in deaths are cocaine, opioids, antidepressants, benzodiazepines, stimulants, and club drugs.8 Among prescription drugs, abuse of psycho-active drugs, especially anti-anxiety and insomnia medications, is rising. Additionally, there has been a dramatic increase in opioid prescriptions for non-cancer related pain. The increase in opioid prescriptions has resulted in an increase in misuse, abuse, diversion, overdose, and deaths. From 1999 to 2013, the death rate from opioid analgesics has nearly quadrupled. Many of these deaths involve another prescription medication, frequently a benzodiazepine.9 Those individuals with chronic pain conditions who initiate opioid therapy with long-acting agents are at a higher risk of unintentional overdose as compared to those given shorter-acting agents. There has been a multifaceted approach to opioid abuse deterrence in the United States. In July 2012, the FDA approved a Risk Evaluation and Mitigation Strategy (REMS) for extended release and long-acting opioids. One element of REMS is the availability of voluntary training programs to licensed prescribers in the United States. There have also been changes to the labeling of extended release or long-acting products with an increase in information related to risk and precautions. Additional efforts to curtail opioid abuse and misuse include development of abuse-deterrent formulations of opioid analgesics, adoption of prescription drug monitoring programs, increased education for patients and health care providers, and cracking down on pill mills and doctor shopping.

PHARMACOLOGY

Knowledge of drug pharmacology, interactions, and expected clinical effects assists in the diagnosis and care of substance abuse victims. A careful medication history for all legal and illegal drugs,
Inhaled hydrocarbons, such as toluene, are rapidly absorbed and easily pass through the lipophilic blood-brain barrier to give an inexpensive high. Illicit drug laboratories have poor quality control, and many drugs are combined or “cut” with other substances to increase profits. Up to 50% of street samples lack the alleged drug. Some additives, such as local anesthetics or sugars, may be innocuous, but others, such as strychnine, may be lethal. Levamisole, a widely available anthelmintic agent, is now a common cocaine adulterant and can result in life-threatening agranulocytosis, leukoencephalopathy, and cutaneous vasculitides. Other drugs, such as PCP, are misleadingly sold as a different drug, such as lysergic acid

including ethanol, may pinpoint the source of an adverse reaction. For example, a variety of agents can increase the effects of cocaine. The co-ingestion of ethanol and cocaine results in an active metabolite, cocaethylene, which can enhance and magnify cocaine’s effects. Serotonin syndrome, manifested by muscle rigidity, hyperthermia, diarrhea, and seizures, may result when sympathomimetic drugs are taken concurrently with other serotonergic drugs, such as selective serotonin reuptake inhibitors. Amphetamines elevate serotonin either directly, by reversible inhibition of monoamine oxidase, or by inhibiting presynaptic catecholamine reuptake. Monoamine oxidase inhibitors can provoke hypertensive crises in patients taking sympathomimetics. Interactions between medications commonly prescribed for patients with human immunodeficiency virus (HIV) infection and recreational drugs may be associated with serious clinical consequences because protease inhibitors and non-nucleoside reverse transcriptase inhibitors (NNRTIs) can inhibit or induce the cytochrome P₄₅₀ system, which could result in either drug accumulation or toxicity or withdrawal reactions. For example, patients maintained with methadone who are subsequently treated with NNRTIs are at risk for development of methadone withdrawal by NNRTI-mediated enzyme induction.

Household products and medications also have abuse potential. For example, dextromethorphan in common cough medications is converted into a substance (dextrorphan) similar to ketamine and phencyclidine (PCP) that causes dissociative effects by antagonizing the N-methyl-D-aspartate (NMDA) receptor. Recreational users describe mild hallucinations and an “out-of-body” state. Some common chemicals in the home and workplace have an intoxicating effect that may be unexpected. Solvents, paint, lacquers, glues, aerosols, refrigerants, and other propellants (Fig. 140.1) are readily accessible for abuse among children and

diethylamide (LSD). Many doses of purported ecstasy (MDMA) actually contained amphetamine drug mixtures or even simple caffeine. Drug combinations and unanticipated additives or substitutions may produce a clinical picture discordant with what the patient claims to have taken.

“Look-alike” drugs may also have toxic effects. Teens in particular may take look-alike or “knock-off” drugs that look like a desired product, such as Ritualin or Cordineid, in the hope of getting high, when in reality they may suffer unanticipated effects from an unrelated medication sold by an unscrupulous dealer.

CLINICAL FEATURES

History

Patients often present claiming a “drug reaction,” but a drug history should be obtained from all patients presenting with altered mental status, acute anxiety or other psychiatric problems, and acute cardiopulmonary or neurologic symptoms. This information should include use of legal and illegal substances, prescription and OTC medications, vitamins, herbs, tonics, and potions. The clinician should distinguish recreational or regular use from suicidal intent.

Parents should be asked what is available in the house, or what they believe their son or daughter took, and when. There are numerous resources available, such as www.drugabuse.gov/drugs-abuse/commonly-abused-drugs-charts, which is sponsored by the National Institute on Drug Abuse, to help decipher street jargon for various agents. Poison centers also are good sources for the names given to various drugs of abuse. However, there is no guarantee that the purported ingestant is pure or unadulterated; therefore, a careful examination may provide the most reliable clues about the exposure. Prehospital personnel, family members, and friends may be able to offer additional information. Patients who are brought from the scene of a club, “rave,” or circuit party with altered mental status may be under the influence of a club drug, such as MDMA (ecstasy), gamma-hydroxybutyrate (GHB), flunitrazepam (Rohipnol), or ketamine. Other club drugs contain gamma-butyrolactone (GBL) or 1,4-butanediol (BD) and are sold on the Internet as precursor molecules to GHB. Grazing parties are a social phenomenon in which teens attending these events bring several random pills from their home medicine cabinet, which are then placed in a large bowl or container. Willing participants at the party will then try various unidentified pills and compare clinical effects.

Injection drug abusers often have infectious complications, such as septic pulmonary emboli, skin or brain abscesses, endocarditis, and HIV or hepatitis-related disease.

Physical Examination

In addition to determination of vital signs, patients should be undressed and completely examined, with particular attention paid to the skin, pupils, and mental status, and evaluated for signs of trauma. Needle or track marks may be found in unusual areas, such as the supraclavicular space. Medicinal patches (eg, fentanyl) may be located under skin folds, or in the genital or rectal areas.

Physical examination includes evaluation for specific toxic syndromes. The presence of diaphoresis, mydriasis, tachycardia, hypertension, abnormal mental status, and urinary retention suggests sympathomimetic toxicity. In comparison, the anticholinergic (antimuscarinic) syndrome may have these same features along with dry mucous membranes. In addition, patients with antimuscarinic delirium tend to be less violent and paranoid than those with sympathomimetic toxicity. The mental status evaluation should address both the level of consciousness and appropriateness of affect. Specific physical findings, such as dental disease, skin abscesses, cardiac murmur, or focal neurologic abnormalities, such as tremor or ataxia, can assist in identification of chronic drug abuse (Table 140.1). Dental disease with extensive caries has traditionally been attributed to methamphetamine use, but it is common with other forms of chemical dependency. The skin provides important clues to substance abuse, such as residue of chemicals or drugs on the hand or face or track marks from injection drug use.

COMPLICATIONS

Illicit drugs produce a wide variety of complications involving all major organ systems. Neurologic complications are especially prominent. A significant percentage of strokes are secondary to drug abuse. Cerebral infarction, cerebral and cerebellar hemorrhage, and subarachnoid bleeding are often secondary to use of sympathomimetics and, occasionally, PCP or heroin. Single generalized tonic-clonic seizures are common with substance abuse, and status epilepticus can occur. Although sympathomimetics such as cocaine and amphetamines are responsible for the majority of seizures, heroin, tricyclic antidepressants, bupropion, and diphenhydramine are high risk. Withdrawal from benzodiazepines and alcohol can also result in seizures, including status epilepticus.

The dangers of substance abuse extend far beyond the toxic effects of a particular drug. Associated hazards include HIV infection, not only secondary to injection but also from the promiscuous lifestyle associated with the drug culture. The prevalence of HIV infection in injection drug users has been estimated at approximately 12% to 17%.

Recent declines in the incidence of HIV infection among injection drug abusers are encouraging, but resurgences have been associated with needle sharing and inadequate methadone treatment. Accompanying this phenomenon is a decrease in hepatitis B and hepatitis C among injection drug users in some cities in the United States. This is probably due to increases in preventive measures, such as needle-exchange programs, condom use, and vaccination for hepatitis B. Almost 20% of cocaine abusers have a positive tuberculosis skin test result. Sexually transmitted disease is common, especially in the sex-for-drugs culture of heroin and crack cocaine. Syphilis, in particular, is endemic among crack abusers.

The lungs are target organs for impurities in intravenous drugs, and pyrogens become trapped in this massive filter. This can produce “cotton fever,” characterized by high fever, tachycardia, and tachypnea 10 to 20 minutes after injection. This is usually a self-limited illness in contrast with the long-term restrictive and obstructive lung diseases with the prolonged intravenous abuse of methylphenidate. Right-sided endocarditis is a frequent sequela of chronic injection drug abuse, and the nonspecific influenza-like symptoms that accompany this disease can mislead the clinician.

In addition to endocarditis and HIV infection, injection drug abusers have septic pulmonary emboli, cellulitis, botulism, tetanus, and other infectious complications. They may have unusual sites of osteomyelitis or septic arthritis involving the spine or sternoclavicular or sacroiliac joints. A diagnosis of spinal epidural abscess, diskitis, or osteomyelitis should be considered in an injection drug user presenting with unexplained back pain.

Psychiatric complications of substance abuse are frequent and include anxiety, depression, suicidal ideation, mood swings, paranoia, and panic attacks. Paranoia and depression and associated suicide attempts are common among stimulant abusers, and hallucinations of parasites under the skin (formication) are frequent in those addicted to amphetamine derivatives and cocaine. Sympathomimetics are strongly associated with aggressive behavior and street crime. More than 50% of penetrating trauma from knife or gunshot wounds is now attributed to drug use.

(particularly methamphetamine) in some communities. Traumatic injuries from motor vehicle collisions are also endemic in substance abusers. Psychedelic drugs, such as LSD and PCP can prompt extreme behavioral changes and violence that can in turn lead to traumatic injuries. On occasion, trauma can be occult, and the unwary physician may overlook wounds in patients whose clinical picture is predominantly drug-induced agitation.

DIFFERENTIAL DIAGNOSES

Many serious illnesses can be confused with the effects of drug abuse, including sepsis, meningitis, encephalitis, head trauma, unintentional poisoning (eg, carbon monoxide), hypothermia, heatstroke, intracranial hemorrhage, complex seizures, and drug withdrawal. Hypoglycemia and other metabolic and endocrine derangements are important considerations. Similarly, drug intoxication should be considered in the differential diagnosis of altered mental status or abnormal vital signs regardless of age. Although patients with decompensated psychiatric disease can present similarly to those with drug intoxication, the hallucinations from psychiatric disease are usually auditory in nature, whereas hallucinations from drug intoxication or withdrawal tend to be visual hallucinations. There are other differences, as well, such as the maintenance of orientation with psychosis, but it nevertheless is difficult for the clinician to clearly differentiate between behaviors and agitation associated with drug abuse and those of decompensated psychiatric disease.

DIAGNOSTIC TESTING

All patients with acute alterations in mental status in whom hypoglycemia is possible require a point-of-care glucose test. Electrolytes and renal function are indicated for patients who are unstable or present with altered mental status. An electrocardiogram is indicated for patients with drug-related chest pain and will identify changes specific to certain drugs and medications, such as prolongation of the QRS or QTc interval in patients with significant toxicity. Arterial or venous blood gas analysis may be useful in assessment of presence of respiratory acidosis, as well as in measurement of oxygenation and ventilation, specifically if a
patient is sedated and hypoventilating. It may also be helpful if there is concern for a co-ingestant that can cause a metabolic acidosis such as salicylates or a toxic alcohol. Rhabdomyolysis, most often seen with psychostimulant abuse, drug-induced hyperthermia, or prolonged periods in the same body position after abuse of sedatives (e.g., barbiturates), is best detected by measurement of serum creatine kinase or myoglobin.18

The use of qualitative toxicology screens is less important than the patient’s history and clinical status. Although unsuspected drugs may be detected on a urine toxicology screen, this knowledge rarely affects acute management of the patient.19 Quantitative levels of suspected substances, such as acetaminophen, acetalsalicylic acid, lithium, and certain anticonvulsants, may be valuable in certain circumstances. A new generation of rapid bedside “drug of abuse” urine toxicology screens utilizing newer techniques, such as liquid chromatography and mass spectrometry, may provide more accurate and timely information.20 There are some special circumstances in which rapid qualitative urine toxicology screening may have some utility. For example, positive urine screens for sympathomimetics can occasionally be found in children presenting with bizarre or abnormal behavior or new-onset convulsions if they have been exposed to these substances in the home environment where they are being used or manufactured. These findings in older children may also assist parents in assessing changing behavior or school performance in some situations.

**MANAGEMENT**

### Agitation

Few antidotes exist for psychoactive drug intoxication, and with a few notable exceptions, treatment is supportive. Violent or agitated patients require rapid sedation. Benzodiazepines are the preferred agents to treat anxiety and agitation, especially if caused by sympathomimetic or hallucinogenic drug intoxication. Treatment options include lorazepam 1 to 2 mg IV, repeated every 10 minutes until the patient is calm or diazepam 5 to 10 mg IV, repeated every 1 to 4 hours. More frequent dosing may be necessary in the setting of seizures or alcohol withdrawal. When the drug-induced agitation has not responded to what the clinician believes to be an adequate dose of a benzodiazepine, an antipsychotic medication should then be added. Butyrophenone antipsychotic agents such as haloperidol and droperidol, are rapidly effective and generally safe for all drug-induced psychosis or agitation states including sympathomimetics. Haloperidol, 2–5 mg IM, may be repeated every 20–30 minutes. Although not approved for intravenous use, this route it widely used and apparently safe. However, the FDA added a warning that “torsade de pointes and QT prolongation have been observed in patients receiving haloperidol, especially when the drug is administered intravenously or in higher doses than recommended.” The sedative dose for droperidol is 2.5–5 mg IM. Droperidol has a box warning from the Food and Drug Administration (FDA) for QT prolongation and potentially torsade de pointes. Most reported cases of butyrophenone-induced dysrhythmias have been in individuals receiving large doses for prolonged periods, such as hours to days, or in elderly populations (older than 60 years of age). These medications lack the respiratory depression potentially caused by other agents and may be beneficial in some cases when sedation is required. For these reasons, the butyrophenones remain effective agents for treatment of drug-induced agitation. We do not recommend the routine use of second-generation or “atypical” antipsychotic agents, such as olanzapine, because there is no evidence of superiority of these agents over the “typical” antipsychotic medications, which have stood the test of time. In a patient felt inappropriate for a typical antipsychotic agent (e.g., listed allergy, prolonged QT), the dose of olanzapine for agitation is 2.5 to 10 mg IM, given every 2 hours up to a maximum of 30 mg. We do not recommend the use of “first generation” phenothiazines, such as chlorpromazine, in the drug-intoxicated patient because of their strong anticholinergic effects and potential to produce hypotension and possibly lower the seizure threshold. Finally, temperature abnormalities, such as severe hyperthermia stemming from substance abuse with sympathomimetics, should be treated with sedation and rapid cooling measures.

### Drug Seeker

As the front line in medical care, emergency departments (EDs) are frequently confronted by patients with drug-seeking behavior, typically for opioids or benzodiazepines. This drug-seeking behavior is described as a compulsion for seeking and taking drugs after prolonged use of a certain drug but also may be motivated by obtaining prescription drugs for the purposes of trafficking (selling) them. The street value of some prescription opioids, such as oxycodone, is greater than that of marijuana and heroin.

Self-admission of drug dependency would provide an excellent screening test, but 90% of patients who abuse opioids deny it.21 A prior history of drug or alcohol abuse may identify patients at risk for abuse of opioids, the most commonly abused agents of the prescription drug seeker.22 Repeated visits for the same complaint, rapid dose escalation, unusual and multiple allergies, and demands for specific agents (often in specific milligram amounts) are all warning signs of potential drug seeking.23 Unfortunately, there is no reliable finding that can consistently identify drug seeking while not penalizing those in true need of analgesics.

Chronic or recurrent pain syndromes (with notable exceptions like renal colic occurring after an interval of months to years) are not acute problems amenable to treatment in, or from, the ED. Patients with these conditions require consistent outpatient treatment from a regular provider or a pain management center. Some hospitals and states are starting to track patients who repeatedly receive opioid prescriptions. The effectiveness of such programs is not yet clear. Some locales have had success with pain guidelines that restrict the use of opioids to proven conditions, with electronic flagging of habitual visitors who present for medical care.24 Such approaches may work if they are done in conjunction with referral to chronic pain clinics or detoxification centers. A multifaceted approach combining counseling, denial of opioid or other psycho-active prescriptions in the ED, and referral to a single pharmacy may dramatically decrease ED visits by frequent users.

Use of a prescription drug monitoring program, which is now available in many states, can also impact emergency clinician ability to recognize the substance abusing patient.25

Finally, pain contracts or explaining to the patient that opioids or other controlled substances are not appropriate may be helpful, but only if other physicians in the group or community agree on such a strategy for a particular patient.

### DISPOSITION

After acute medical issues have been managed, substance abusers should be asked whether they would like help in overcoming their addiction. Studies show that intervention may be most successful for abusers of heroin, non-prescribed methadone, and benzodiazepines. Users of crack cocaine or methamphetamine appear to be more resistant to treatment. Offering symptomatic relief from withdrawal with short courses of medications, including antianemics, antidiarrheals, and benzodiazepines, when indicated, may improve the patient’s ability to sustain sobriety. Any patient with suicidal ideations or intent warrants immediate psychiatric evaluation. Those with a history of substance abuse requesting
assistance with sobriety should be given resources or a social work evaluation if available. If inpatient resources are not available or not deemed required, discharging the patient in the care of a family member or reliable friend is ideal.

Patients with acute intoxication and altered mental status that does not normalize after a period of observation would require admission or a prolonged observation period. Those under the influence of sympathomimetic drugs (such as, cocaine or methamphetamine) may develop delayed complications (such as, rhabdomyolysis) that warrant inpatient hospitalization. After the patients’ acute intoxication has resolved, withdrawal symptoms may develop requiring hospitalization and adjunctive medications, such as benzodiazepines. Admission to the intensive care unit may be needed in certain situations, such as severe hyperthermia, intractable convulsions, respiratory depression necessitating airway support, myoglobinuric renal failure, severe metabolic acidosis, or severe agitation requiring large doses of sedatives.

KEY CONCEPTS

- Substance abuse can affect people from all socioeconomic groups and all ages.
- For the majority of patients with toxin-induced violent behavior, intramuscular butyrophenones (such as, haloperidol) are safe and rapidly effective sedating agents. With suspected sympathomimetic (eg, cocaine and amphetamines) intoxication, benzodiazepines (such as, lorazepam) should be used.
- Presentation to an ED with a complication of substance abuse may be a "teaching moment." Substance abusers should be offered drug treatment services.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
140.1. The toxic syndrome for anticholinergic overdose is similar to sympathomimetic toxicity and includes all of the following signs with the exception of:

A. Altered mental status
B. Diaphoresis
C. Hyperthermia
D. Increased heart rate
E. Urinary retention

Answer: B. Anticholinergic (antimuscarinic) syndrome includes all of the signs above except for diaphoresis. Typically, anticholinergic poisoning presents with dry skin and mouth but otherwise has similar features to sympathomimetic toxicity. Sympathomimetic overdose often presents with diaphoresis. Anticholinergic patients are also less paranoid and violent.

140.2. What percentage of emergency department (ED) patients are in need of substance abuse treatment?

A. 1%
B. 10%
C. 25%
D. 50%
E. 75%

Answer: C. Approximately 1% of ED patients have a formerly recorded diagnosis of substance abuse, but about 25% are actually in need of substance abuse treatment. Many patients are in denial about their dependency or hiding their substance abuse problems and will avoid talking about this. Because substance abuse increases the risk for injury or illness, these patients are at much higher risk for the need for emergency care than the general population.
Ethyl alcohol (ethanol) is ubiquitously consumed worldwide on a daily basis and contributes to a multitude of disease process, cancers, and traumatic events. Although ethanol certainly can be viewed as a toxic alcohol, its use, abuse, and related conditions are discussed in Chapter 142. This chapter will focus on methanol, ethylene glycol (EG), and isopropyl alcohol (isopropanol).

METHANOL

Methanol (methyl alcohol; CAS 67-56-1; H₃COH) is a clear, volatile, colorless, slightly sweet-tasting alcohol at room temperature. It is also known as wood alcohol due to being distilled from wood in the 1920s and 1930s. Methanol is mainly used as a solvent or octane booster in gasoline. It is manufactured frequently as an intermediate in chemical reactions. As a solvent, it is present in many items found in the home, including cleaning solutions, adhesives, enamels, stains, dyes, and paint removers. Methanol is also commonly found in windshield wiping fluid, antifreeze (particularly brake line antifreeze), embalming fluid, and fuel for tile, colorless, slightly sweet-tasting alcohol at room temperature.

Many mass methanol poisonings have occurred throughout history, including recent outbreaks in Estonia (2001), Norway (2002–2004), the Czech Republic (2012), Libya (2013), and Kenya (2014). Despite vast knowledge and experience with methanol, these outbreaks demonstrate the diagnostic challenge and difficulty in treating these patients. In 2013, 1747 single substance exposures to methanol were reported to US poison centers. The vast majority were unintentional exposures (88.7%), with few major complications (<1%) and only 8 deaths. These data, however, rely on voluntary reporting and likely underrepresent the true burden of methanol exposures and mortality outcomes from forensic data in the United States.

Principles of Toxicology

Methanol is rapidly absorbed from the gastrointestinal (GI) tract, with an average absorptive half-life of 5 minutes, and reaches peak concentration in 30 to 60 minutes. Inhalation of methanol from carburetor cleaning fluid results in toxicity necessitating antidotal therapy and hemodialysis. Transdermal exposure can lead to significant methanol exposure and toxicity as well. High-risk occupations for exposure to methanol include painting, varnishing, lithography, printing, and glazing.

Methanol itself has low toxicity, but its metabolism results in toxic metabolites, in particular formic acid, which dissociates into formate and hydrogen ions. Methanol is primarily metabolized in the liver by alcohol dehydrogenase (ADH) into formaldehyde. Formaldehyde is then metabolized by aldehyde dehydrogenase (ALDH) very rapidly, with a half-life of 1 to 2 minutes, into formic acid (Fig. 141.1). Formic acid can combine with tetrahydrofuroate (THF) to form 10-formyl THF, which can be metabolized into carbon dioxide and water.

Elimination of methanol is mainly characterized via zero-order kinetics in the poisoned patient but does have first-order metabolism at very low concentrations, with an elimination half-life of about 2 to 3 hours. Small amounts of methanol are eliminated by the renal and pulmonary systems.

At toxic concentrations, the elimination half-life of methanol is nearly 24 hours. The metabolite, formic acid, has a half-life of nearly 20 hours. With ADH inhibition by concurrent consumption of ethanol or administration of fomepizole, the half-life of methanol extends upward to more than 50 hours. With dialysis, the half-life of methanol is approximately 200 minutes.

Formic acid will accumulate due to its slower metabolism as it exceeds the elimination rate. Formic acid binds iron efficiently, resulting in mitochondrial cytochrome oxidase inhibition, and interferes with oxidative metabolism in a manner similar to that of cyanide, carbon monoxide, and hydrogen sulfide. The dissociation of formic acid into formate and hydrogen ions leads to acidosis. The interference of oxidative metabolism, combined with acidosis, further promotes lactate production and worsens the acidotic state. Decreasing pH promotes formic acid diffusion across cell membranes, in particular to the central nervous system (CNS). Also, inhibition of cytochrome oxidase by formic acid is potentiated with decreasing pH. The net effect of this vicious cycle is tissue hypoxia and inhibition of intracellular respiration. Further mechanisms of toxicity include free radical formation, lipid peroxidation, and impairment of antioxidant reactions.

Formic acid uniquely targets the optic disk of the retina and retrolaminar optic nerve, potentially due to the high amount of blood and cerebrospinal fluid (CSF) flow through the choriocapillaris. These cells are more susceptible to cellular hypoxia due to low levels of mitochondria and cytochrome oxidase. Inhibition of mitochondrial cytochrome oxidase results in decreased adenosine triphosphate (ATP) production, leading to myelin sheath damage and loss of vision. Worsening acidosis again potentiates these effects by enhancing the diffusion of formic acid across cell membranes into the neurons.

The basal ganglia and subcortical white matter are affected by formic acid in a similar manner to the ocular toxicity. Neuroimaging and autopsy findings classically demonstrate putamen hypodensity, with hemorrhages and necrosis. Bilateral putamen changes are not specific to methanol toxicity and can be found in Wilson’s disease, Leigh’s disease, Kearns-Sayre syndrome, toxic encephalopathy (eg, 1,1,1-trichloroethane, carbon monoxide, cyanide, hydrogen sulfide), hemolytic-uremic syndrome, and hypoxic-ischemic injury. The severity of findings and extent of necrosis on imaging do not necessarily correlate with clinical outcome. The vulnerability of the basal ganglia to formic acid toxicity may be due to its high metabolic activity, with poor venous drainage and inadequate arterial flow.

Clinical Features

Clinical signs and symptoms of methanol intoxication typically involve the GI tract, CNS, and the eyes. Initially, patients present in a manner similar to other alcohol ingestions, with GI irritation, inebriation and CNS depression. Methanol has a less inebriating effect than ethanol but causes similar slurred speech, ataxia, confusion, and CNS depression. Abdominal discomfort and
transient, and vision recovers. Optic atrophy and optic neuropathy suggest a poor prognosis for visual recovery. The incidence of ophthalmologic abnormalities correlates directly with the degree of acidosis.

As acidosis progresses, a compensatory tachypnea develops. Acidosis can be profound, with many patients presenting with an arterial pH less than 7 and serum bicarbonate level less than 10 mEq/L. Tachycardia is often noted, but patients rarely have significant cardiac dysrhythmias. Also, shock, seizures, myoglobinuria and rhabdomyolysis have been reported. Death typically results from respiratory failure and sudden respiratory arrest, with cerebral edema and multiorgan failure.

Prognosis after methanol ingestion correlates with the degree of acidosis, time to presentation, and initiation of treatment. The strongest predictor of morbidity and mortality is the degree of acidosis, with high mortality rates observed at a pH less than 7. A
Admittedly, hyperlipidemia and hyperproteinemia cause an ethylene glycol; see Table 141.1). Worsening acidosis, despite cyanide, metformin, toluene, paraldehyde, propylene glycol, and toxins (eg, salicylates, isoniazid, iron, carbon monoxide, alcoholic ketoacidosis, uremia, inborn errors of metabolism, and toxins (eg, salicylates, isoniazid, iron, carbon monoxide, cyanide, metformin, tolulene, paraldehyde, propylene glycol, and ethylene glycol; see Table 141.1). Worsening acidosis, despite adequate fluid hydration and no evidence of underlying ischemia producing lactic acidosis, should raise the concern for toxic alcohol ingestion. The presence of a so-called double gap (elevated osmolar and anion gaps) is classically described for toxic alcohol ingestion. Many other situations, however, can cause a similar picture, including diabetic ketoacidosis, alcholic ketoacidosis, renal failure, multiple organ failure, and septic shock (see Table 141.1). This double gap picture is also dependent on the timing of presentation because early presenters will have only an osmotically active parent compound and late presenters will have acidosis without an elevated osmolar gap^11 (Fig. 141.2).

The development of ocular manifestations with worsening acidosis is a strong indicator for methanol poisoning. Other toxins, however, can cause ophthalmologic conditions and blindness such as cinchonism with quinine intoxication, but this lacks the elevated osmolar and anion gaps. Cortical blindness can occur with various causes of toxic leukoencephalopathy, including carbon monoxide, hydrocarbons, steroids, metals (organic mercury), and various chemotherapeutic agents (eg, carboplatin, cisplatin).

### Diagnostic Testing

The classically described presentation of toxic alcohol ingestion includes an anion gap metabolic acidosis and an elevated osmolar...
PART IV  Environment and Toxicology  |  SECTION TWO  Toxicology

1832

In systems using SI units, there are no corrections, and the various serum levels are simply added or subtracted. The normal osmolar gap has been arbitrarily defined as normal if it is less than 10 mOsm. However, a wide range of osmolar gaps occurs in the population, ranging from −15 to +10 mOsm. As a result, individuals who begin with a negative osmolar gap can have significantly elevated concentrations of toxic alcohols but have a so-called normal osmolar gap. Many other substances can contribute to an osmolar gap and can be misleading. Also, if patients are acidic, the parent compound (methanol, ethylene glycol) has been metabolized into its respective acid and does not contribute to the osmotic load. Thus, a normal osmolar gap cannot exclude toxic alcohol ingestion. Methanol, however, is more likely than EG to cause a falsely elevated the AG; the AG can be corrected by using the Figge equation:

\[ AG = [Na^+] - ([HCO_3^-] + [Cl^-]) \]

with a normal AG of 8 to 12 mEq/L. Decreased albumin can falsely elevate the AG; the AG can be corrected by using the Figge equation:

\[ AG \text{ corrected} = AG + (2.5 \times (4.4 - \text{measured serum albumin})) \]

Mortality correlates highly with the degree of acidosis and formate concentration rather than with a specific methanol concentration. Visual dysfunction occurs with a formate concentration greater than 20 mmol/L. Indicators for a poor prognosis include a formate concentration more than 50 mg/dL and a pH less than 7.4.

Many formulas exist for calculating serum osmolarity but the most commonly used is the following:

\[ \text{Osmolar gap} = \text{measured osmolarity (mOsm/L)} - \text{calculated osmolarity (mOsm/kg)} \]

In clinical practice however, initiate fomepizole therapy with a strong clinical suspicion for serious ingestion, and send for confirmatory labs, because a delay in ADH blockade can lead to the development of acidosis and deleterious consequences. Fomepizole dosing involves a loading dose of 15 mg/kg followed by 10-mg/kg doses bid, up to 48 hours. After 48 hours, give 15 mg/kg bid because repeated dosing of fomepizole induces its own cytochrome P-450 metabolism. The fomepizole dosing frequency does need to be adjusted with hemodialysis (Box 141.1). Side effects of fomepizole include headache, nausea, dizziness, phlebitis, and reversible liver transaminase level elevation. One case of hypotension and bradycardia due to the rapid infusion of fomepizole has been described.

If ethanol is used to inhibit ADH, maintain serum ethanol concentrations between 100 and 150 mg/dL. The affinity of ADH for ethanol is 10 times greater than for methanol. Ethanol dosing

Management

Alcohols are rapidly absorbed from the GI tract, so GI decontamination has limited to no value. Gastric suctioning via a nasogastric or orogastric tube may be considered in a large suicidal volume exposure (eg, an entire bottle of windshield washer fluid or antifreeze) in someone who presents immediately after ingestion, but there is no evidence to support routine use. Activated charcoal is not indicated for toxic alcohol ingestions. Aside from standard stabilization and resuscitation, the main priorities in toxic alcohol exposure are correction of acidosis, inhibition of the production of toxic metabolites, and elimination of the parent alcohol and its toxic metabolites. Therapy should be initiated based on strong clinical suspicion; treatment should not be delayed while waiting for specific serum concentrations to be determined.

Because the degree of acidosis correlates with severity and outcome, treat a serum pH less than 7.3 with intravenous (IV) sodium bicarbonate in and attempt to normalize it. Worsening acidosis from formic acid accumulation potentiates mitochondrial cytochrome oxidase inhibition and anaerobic metabolism, also generating a lactic acidosis. Based on supporting patient data, correction of acidosis likely improves outcomes and ophthalmologic symptoms. Bicarbonate can be administered via intermittent boluses, combination of a bolus and infusion, or infusion alone, based on the severity of symptoms. Administer bolus sodium bicarbonate at 1 to 2 mEq/kg and infuse 150 mEq/L of sodium bicarbonate in 5% dextrose at 1.5 to 2 times the maintenance fluid rate until normalization of the serum pH (7.35–7.45). Large amounts of bicarbonate may be necessary for even partial correction of acidosis due to metabolism of the parent alcohol into its toxic acid. With bicarbonate administration, monitor for the development of hypernatremia and hypokalemia. The use of bicarbonate should not deter definitive elimination of the parent alcohol and its toxic metabolites via hemodialysis.

Prevent the further production of formic acid by inhibiting ADH with fomepizole (methylpyrazole, 4-MP) or ethanol. Fomepizole is preferable due to its safety profile and ease of administration, with a sevenfold reduction in adverse drug event rate versus ethanol. No contraindication exists for fomepizole use except for a severe allergic reaction, but currently there have been no reported cases. Specific indications for initiating ADH blockade are a documented methanol or EG concentration more than 20 mg/dL, documented history of methanol or EG ingestion with an osmolar gap more than 10 mOsm/L, or suspected methanol or EG ingestion with and arterial pH less than 7.3, serum carbon dioxide level less than 20 mmol/L, or oxalate crystalluria.

In clinical practice however, initiate fomepizole therapy with a strong clinical suspicion for serious ingestion, and send for confirmatory labs, because a delay in ADH blockade can lead to the development of acidosis and deleterious consequences. Fomepizole dosing involves a loading dose of 15 mg/kg followed by 10-mg/kg doses bid, up to 48 hours. After 48 hours, give 15 mg/kg bid because repeated dosing of fomepizole induces its own cytochrome P-450 metabolism. The fomepizole dosing frequency does need to be adjusted with hemodialysis (Box 141.1). Side effects of fomepizole include headache, nausea, dizziness, phlebitis, and reversible liver transaminase level elevation. One case of hypotension and bradycardia due to the rapid infusion of fomepizole has been described.

Fomepizole dosing involves a loading dose of 15 mg/kg followed by 10-mg/kg doses bid, up to 48 hours. After 48 hours, give 15 mg/kg bid because repeated dosing of fomepizole induces its own cytochrome P-450 metabolism. The fomepizole dosing frequency does need to be adjusted with hemodialysis (Box 141.1). Side effects of fomepizole include headache, nausea, dizziness, phlebitis, and reversible liver transaminase level elevation. One case of hypotension and bradycardia due to the rapid infusion of fomepizole has been described.

If ethanol is used to inhibit ADH, maintain serum ethanol concentrations between 100 and 150 mg/dL. The affinity of ADH for ethanol is 10 times greater than for methanol.

Ethanol dosing
is complex and can cause worsening CNS and respiratory depression, with hypotension, vomiting, phlebitis, and hypoglycemia, particularly in children or malnourished individuals.\(^{11,12}\) Given the widespread availability of fomepizole and its safety profile versus that of ethanol, the dosing of IV ethanol will not be discussed here because its routine use is not recommended. With ADH inhibition, the half-life of methanol is significantly extended upward of 50 hours.\(^{2}\) Patients who present early after methanol ingestion without acidosis can potentially be treated with ADH and may have prolonged hospitalizations due to the extended half-life of the parent compound.\(^{12}\)

Elimination of the parent alcohol via hemodialysis (HD) is the mainstay of therapy in severe toxic alcohol ingestions, and consultation with a regional poison center or medical toxicologist will help determine whether the patient is a candidate. HD serves multiple purposes in that it removes the parent alcohol and its metabolites, corrects acidosis, and aids in fluid management and cardiovascular stabilization. Additionally, it can shorten the course of hospitalization, particularly in methanol ingestions, due to its long half-life.

HD is indicated for acidosis (pH < 7.3), renal failure, vision abnormalities with methanol exposure, electrolyte imbalances unresponsive to conventional therapy (ie, hyperkalemia), hemodynamic instability, and methanol or EG concentration more than 50 mg/dL.\(^{11}\) Traditional endpoints for discontinuing HD or ADH inhibition are a normal acid-base status and methanol-EG concentrations less than 20 mg/dL.\(^{11,12}\) Ophthalmologic disturbances are not an indication for continued dialysis after correction of the acid-base disturbance and removal of methanol. There is no specific treatment for methanol-induced persistent optic nerve injury.\(^{12}\) Formic acid is converted to carbon dioxide and water via tetrahydrofolate synthetase, so folinic acid (leucovorin) may aid in formic acid elimination, but there have been no human trials to support its benefit.\(^{1,12}\) The recommended dose is 50 mg of folinic acid IV every 4 to 6 hours until methanol has been eliminated and the acidosis resolves.\(^{1,12}\) The use of folinic acid (leucovorin) should not deter emergent HD if indicated.

### Disposition

Admission is generally necessary for patients being treated for methanol exposure. Consult with nephrology early for possible HD. If HD is not available, initiate ADH inhibition and transfer the patient to an institution where dialysis is available. Consult the regional poison center (1-800-222-1222) or a medical toxicologist to guide management. Consult an ophthalmologist to evaluate visual fields and the retina fully for methanol-induced ocular injury within 24 hours. Patients with a methanol concentration less than 20 mg/dL and no clinical symptoms or laboratory abnormalities may be discharged. If the patient has psychiatric issues or intent of self-harm, a psychiatric consultation is indicated.

#### ETHYLENE GLYCOL

Ethylene glycol (ethane-1,2-diol, CAS 107-21-1, C\(_2\)H\(_6\)O\(_2\)) is a colorless, odorless, sweet-tasting liquid. It is a common component of antifreeze and de-icing solutions because it lowers the freezing point of water. Additional sources of EG include hydraulic brake fluids, industrial solvents, foam stabilizer, paints, and cosmetics. Because EG has a sweet taste, it is often substituted for ethanol and has led to mass poisonings, including during World War II and the 1973 Arab-Israeli conflict. In 2013, 5956 single substance exposures to EG were reported to US poison centers. Most of these were unintentional (83%) but resulted in roughly 10% of patients having moderate to severe effects and a total of 16 deaths.\(^{3}\) Like methanol, these data rely on voluntary reporting and likely underestimate the true burden of EG exposures and mortality outcomes.

### Principles of Toxicology

Ethylene glycol is rapidly absorbed from the GI tract; peak blood levels occur within 1 to 4 hours after ingestion. EG is highly water-soluble and, unlike methanol or isopropanol, is not volatile at room temperature. Transdermal and pulmonary absorption of EG are extremely limited, and toxicity from these routes of exposure is not expected or observed.

Metabolism of EG primarily occurs in the liver via the conversion of ADH into glycoaldehyde, which is rapidly converted by ALDH into glycolate. Glycolate is further metabolized into glyoxylic acid (glyoxylate) and oxalic acid (see Fig. 141.1). The conversion of glycolate into glyoxylate is slow, and the accumulation of glycolate generates a profound metabolic acidosis. Pyridoxine and thiamine are cofactors in the metabolism of glyoxylate but, given the slow conversion of glycolate to glyoxylate, these cofactors likely do not contribute significantly to EG detoxification. A small amount of oxalate will precipitate with calcium to form calcium oxalate crystals. These metabolic oxidation steps result in the conversion of nicotinamid adenine dinucleotide (NAD\(^+\)) to nicotinamide adenine dinucleotide (NADH), which converts pyruvate to lactate and generates a lactic acidosis.

Calcium oxalate crystals precipitate in the proximal renal tubules and are the main contributing factor in the development of acute tubular necrosis and renal failure. Calcium oxalate deposits also occur in the brain, intestinal mucosa, lungs, heart, and spleen, although the contribution of these deposits to the clinical picture is less clear. Further findings of EG toxicity include diffuse petechial hemorrhages in the heart, lungs, and brain, as well as the development of cerebral edema. Myonecrosis and rhabdomyolysis can occur. The chelation of calcium by oxalate can lead to systemic hypocalcemia.
Elimination of EG occurs mainly in the liver but roughly 20% to 25% of EG is excreted unchanged in the urine. The reported half-life of EG ranges from 3 to 9 hours, but when metabolism is inhibited by ethanol or fomepizole, the half-life increases up to 20 hours. With dialysis, the half-life of EG is about 2 to 3 hours, depending on flow rates.

Clinical Features

The clinical picture of EG toxicity is typically divided into three stages: (1) acute neurologic stage; (2) cardiopulmonary stage; and (3) renal stage. As with methanol, delayed neurologic sequelae are described. An extreme amount of clinical variability occurs, stages may overlap, and mortality may occur at any stage. Poor prognostic factors at admission include hyperkalemia, severe metabolic acidosis, renal failure, seizures, coma, and delays in treatment. Seizures are highly prognostic for death. The co-ingestion of ethanol can delay the onset of symptoms.

EG is a gastric irritant and can produce nausea and vomiting shortly after ingestion. The acute neurologic stage occurs over 30 minutes to 12 hours after ingestion with EG, producing inebriation and euphoria similar to ethanol. In severe poisonings, CNS depression can progress to coma, hypotonia, and seizures. Additional findings include nystagmus, ataxia, and myoclonic jerks. Cerebral edema can develop from calcium oxalate crystal deposition and cytotoxic damage contributing to CNS depression.

The cardiopulmonary stage occurs 12 to 24 hours after ingestion, with patients developing tachycardia with a severe metabolic acidosis and compensatory tachypnea. The acidosis occurs from the generation of glycolic acid. Hypoxia with pulmonary edema and acute respiratory distress syndrome (ARDS) can cause hypoxia. Multiorgan failure with circulatory collapse can occur, and most deaths ensue during this stage.

The renal stage occurs 24 to 72 hours postingestion with the development of acute renal failure (ARF) from calcium oxalate crystal deposition. Conscious patients may complain of flank pain and have costovertebral tenderness. Hematuria and proteinuria can occur. Renal failure can be anuric, oliguric, or nonoliguric. Renal dysfunction frequently necessitates HD and, in some cases, for months after exposure. Renal function usually returns to normal following EG intoxication, but occasionally some renal damage can be permanent. Long-term hemodialysis is rarely necessary.

Delayed neurologic sequelae commonly present as a bulbar palsy from 5 to 20 days after ingestion, with cranial nerve VII being most commonly implicated. Other cranial nerve involvement has been documented; clinical findings include ophthalmoplegia, diplopia, nystagmus, facial droop, facial sensory loss, hearing loss, dysphagia, and vertigo. The term facial auditory nerve oxalosis has been used to describe this delayed syndrome and its predilection to affect cranial nerves VII and VIII on autopsy. In addition to the cranial nerves, an autonomic nerve dysfunction has been described, with postural hypotension and gastroparesis.

The exact pathogenesis for these neurologic findings is unclear, but postulated mechanisms include calcium oxalate deposition resulting in mechanical nerve injury, inflammatory response causing nerve dysfunction, and depletion of thiamine and pyridoxine cofactors. Neuroimaging studies can demonstrate the focal infiltration of calcium oxalate with inflammation and necrosis of the basal ganglia.

Diagnostic Considerations

Differential Diagnoses

The differential diagnoses for EG intoxication is broad and similar to methanol. See earlier, “Methanol: Differential Diagnoses,” for a more in-depth explanation, especially regarding the initial presentation of inebriation and AMS, proceeding through elevated osmolar and anion gaps (see Table 141.1). Unlike methanol, however, the hallmark of EG toxicity involves renal failure with calcium oxalate crystalluria. Many other substances cause ARF, including antimicrobials (eg, aminoglycosides, vancomycin, sulfa-based drugs, ciprofloxacin, penicillins, polyimixins), nonsteroidal antiinflammatory drugs, angiotensin-converting enzyme inhibitors, angiotensin II receptor blockers, HMG-CoA reductase inhibitors, antivirals (eg, acyclovir, foscarnet, antiretrovirals), amphotericin B, chemotherapeutics (eg, methotrexate, cisplatin, ifosfamide), diethylene glycol (DEG), bisphosphonates, radiocontrast media, metals, proton pump inhibitors, lithium, and acetaminophen. Calcium oxalate crystalluria is therefore not specific for EG and is only present in up to 50% of cases of EG ingestion. Healthy individuals with excess dietary intake of vitamin C or foods rich in oxalate (eg, garlic, tomatoes, spinach, rhubarb, and tea) may have incidental calcium oxalate crystalluria.

Xenobiotic-induced hypocalcemia can occur from proton pump inhibitors, bisphosphonates—and other phosphate-containing substances, such as laxatives and sodium phosphate)—loop diuretics, glucocorticoids, calcitonin, cisplatin, pentamidine, interferon-alfa, fluorides (eg, hydrofluoric acid), citrate, phenytoin, phenobarbital, carbamazepine, estrogens, and ethylenediaminetetraacetic acid. Hypocalcemia and calcium oxalate crystalluria, however, strongly suggests EG toxicity. Ultimately, the definitive diagnosis requires laboratory confirmation of the presence of EG.

Diagnostic Testing

Diagnostic testing for EG is similar to that for methanol; for a more detailed discussion of AG acidosis and elevated osmolar gap calculations, see earlier, “Methanol: Diagnostic Testing.” The contribution of EG to the osmolar gap is relatively small compared to other alcohols, and an EG concentration of 50 mg/dL will only cause an 8- to 10-mOsm rise in the osmolar gap. Thus, an elevated osmolar gap can suggest EG ingestion, but a normal gap does not exclude it.

Calcium oxalate crystalluria can be of two major forms, needle-shaped calcium oxalate monohydrate or polyhedron-shaped calcium oxalate dihydrate crystals. The calcium oxalate monohydrate crystals may be mistaken for hippuric acid crystals. Crystals can be found in the urine 4 to 8 hours after exposure. Additional urinary findings include hematuria and proteinuria.

Fluorescein dye is often added to antifreeze agents to assist in the detection of radiator leaks, so patients who ingest antifreeze

![Fig. 141.3. Calcium oxalate crystals. Illustrated are calcium oxalate monohydrate (A) and dihydrate (B) crystals in the urine. The monohydrate whewellite crystals typically are needle-like or dumbbell-shaped and strongly birefringent, whereas the dihydrate weddellite crystals are octahedral, envelope-shaped, and weakly birefringent.](image-url)
EG-containing agents may exhibit urinary fluorescence under a Woods lamp. Urinary fluorescence, however, is neither specific nor sensitive for diagnosing or excluding EG intoxication. The fluorescence of gastric contents soon after EG ingestion may be more definitive.

The EG concentration itself does not predict severity as much as it depends on the timing of presentation and initiation of intervention. Serum EG concentrations more than 50 mg/dL, however, are associated with serious ingestion and toxicity. The degree of acidosis (particularly a pH < 7.2–7.3) does predict an increase in the creatinine level and mortality outcome. A peak EG concentration less than 20 mg/dL is not associated with significant toxicity.

In EG intoxication, the serum glycolate concentration is the driving force for acidosis. Glycolate concentrations more than 10 mmol/L are strongly associated with severe CNS toxicity and mortality and have 100% sensitivity for predicting ARF. Patients with glycolic acid levels less than 8 to 10 mmol/L are unlikely to develop ARF. Serum glycolate concentrations, however, are not readily available in a timely fashion to aid in most clinical situations.

Management

Many of the management principles of EG toxicity overlap with those of methanol. See earlier, “Methanol: Management” for additional information. EG, like methanol, is rapidly absorbed from the GI tract; thus, gut decontamination has a limited to no role in EG ingestion. Correct metabolic acidosis with sodium bicarbonate (pH < 7.3) because this may increase the urinary excretion of EG and delay calcium oxalate–induced ARF. Initiate ADH blockade, preferably with fomepizole, as soon as possible to prevent the development of toxic metabolites (Boxes 141.1 and 141.2). Ethanol therapy can be used if fomepizole is unavailable, although its routine use is not recommended. Consider HD for the indications stated earlier, particularly for an acid-base imbalance and renal failure. EG, however, has a shorter half-life than methanol, and patients without acidosis or renal compromise can be managed with fomepizole alone, thus preventing the need for HD in adult and pediatric patients. Continue treatment until EG concentrations are less than 20 mg/dL and a normal acid-base status is present.

Pyridoxine and thiamine are cofactors in EG metabolism. Pyridoxine aids in the conversion of glyoxylate metabolism to glycine. Thiamine stimulates conversion of glycolic acid to G-hydroxy-D-ketopimelic acid (see Fig. 141.1). No clinical data, however, support the effectiveness of the use of these cofactors in otherwise healthy patients with EG ingestion. These cofactors should be given to patients with vitamin deficiencies, such as alcoholics abd malnourished individuals. The recommend adult doses are thiamine, 100 mg qid, and pyridoxine, 50 mg qid, for 2 days. If patients have symptomatic hypocalcemia (interval changes on the electrocardiogram and dysrhythmias), replete with calcium gluconate or calcium chloride, as needed.

Disposition

Admission is generally necessary for patients being treated for EG exposure. Consult nephrology early for possible HD. If HD is not available, initiate ADH inhibition and transfer the patient to an institution where dialysis is available. Consult the regional poison center (1-800-222-1222) or a medical toxicologist to guide management. Patients with an EG concentration less than 20 mg/dL and no laboratory abnormalities or clinical symptoms may be discharged. If the patient has psychiatric issues or intent for self-harm, a psychiatric consultation is indicated.

Principles of Toxicology

Isopropyl alcohol is rapidly absorbed from the GI tract; peak plasma concentrations occur within 30 minutes. Oral ingestion is the major route of exposure, but absorption can occur transdermally, rectally, or via inhalation. Children are especially susceptible to systemic symptoms from the dermal application of IPA used to reduce fever.

Metabolism occurs primarily in the liver by ADH into acetone. Acetone is metabolized to acetal (hydroxyaceton) by acetone monoxygenase (see Fig. 141.1). Further metabolic products include propylene glycol, methylglyoxal, lactate, formate, and acetate. Many of these minor metabolic products are then converted to glucose. Acetone reaches a peak plasma concentration from 7 to 30 hours postexposure and has a half-life of up to 24 hours. IPA follows first-order kinetics, with a half-life of 2.5 to 8 hours. ADH inhibition increases the half-life to 16 to 27 hours. Elimination primarily occurs via the kidneys, with up to 20% of IPA excreted unchanged in the urine.

Isopropyl alcohol directly acts as a CNS depressant and is considered to be twice as inebriating as ethanol. Acetone can also contribute to CNS depression. A concomitant respiratory depression can occur with profound CNS depression. With larger doses, peripheral vasodilation and decreased cardiac inotropy can cause hypotension. Topical exposure leads to corneal de-epithelialization, with dermal irritation.

Clinical Features

Isopropyl alcohol irritates mucosal surfaces, and GI effects typically occur early after ingestion. Nausea, vomiting, and abdominal pain typically ensue, but hemorrhagic gastritis, hematemesis, and significant blood loss can result with larger ingestions. As with other alcohols, pancreatitis is a potential complication. Aspiration of IPA can cause hemorrhagic tracheobronchitis and pulmonary edema.

CNS depression ranges from lethargy to stupor or coma. Headache, dizziness, ataxia, hypotonia, hyporeflexia, dysarthria, and seizures have been reported. Pupil size is variable, but miosis is commonly observed. Loss of consciousness is associated with respiratory depression, hypoxia, and aspiration pneumonitis. Hypotension and hypothermia can occur with very large ingestions. Hypotension signifies severe poisoning with increased mortality risk. Injuries from prolonged immobilization with CNS depression can lead to compartment syndrome and rhabdomyolysis. Myoglobinuria can cause ARF. Hypoglycemia has not been reported with IPA as it has for other alcohols. Dermal contact causes a defatting dermatitis with drying and cracking of the skin, and pediatric patients can sustain chemical burns. Ketosis without acidosis is a classic finding in IPA ingestion.
Diagnostic Considerations

Differential Diagnoses

Patients with significant IPA ingestion appear intoxicated. IPA will elevate the osmolar gap but, unlike methanol and ethylene glycol, not the anion gap. See earlier, “Methanol: Differential Diagnoses” for causes for AMS and an elevated osmolar gap. As IPA is converted to acetone, ketosis will occur. Ketosis is present in conditions such as diabetic ketoacidosis, alcoholic ketoacidosis, starvation ketosis, salicylism, and cyanide and acetone ingestion. ARF can develop from rhabdomyolysis but the differential for ARF is extensive (see earlier).

Diagnostic Testing

The most common laboratory abnormality is ketosis without acidosis and euglycemia. As IPA is metabolized, acetone accumulates. Acetone does not elevate the anion gap but IPA and acetone do contribute to the osmolar gap. Acetone can be detected within 30 minutes in serum and within 3 hours in urine postexposure. Acetone can interfere with the assay for creatinine and cause a pseudo–renal failure measurement with an isolated elevated creatinine but normal blood urea nitrogen (BUN) level. If patients are hypotensive however, from a large IPA ingestion, a lactic acidosis can occur, which can then cause a confounding anion gap acidosis. The measurement of the IPA concentration is the definitive method of diagnosis. Occasionally, IPA can be detected in patients with acetemia not exposed to IPA because acetone is converted to IPA in vivo. Serum concentrations of IPA do not correlate well with clinical outcomes—deaths have been reported with concentrations as low as 20 mg/dL. The scant data available suggest that a concentration more than 50 mg/dL is associated with toxicity, and some authors have suggest HD for levels greater than 400 mg/dL although there has been no clear evidence for these recommendations. The clinical status of the patient should direct the necessary care.

Management

Supportive care is the mainstay of therapy for IPA ingestion. There is no role for GI decontamination. Wash the skin with soap and water for dermal contamination. Provide proton pump inhibitors (e.g., pantoprazole, 80 mg IV push and a drip at 8 mg/hr for 72 hours, or until the patient can tolerate oral foods and fluids) for hemorrhagic gastritis. Consult gastroenterology for endoscopy to exclude other causes of upper GI bleeding or to intervene for persistent bleeding causing hemodynamic instability, necessitating transfusion, or worsening clinical scenario. For deeply comatose patients, airway protection is indicated. Hypotension generally responds to IV crystalloid solution. For significant hypotension, initiate 1 to 2 L of normal saline as a bolus infusion, followed by repeated 500-mL boluses at 30-minute intervals until a mean arterial pressure (MAP) of 65 mm Hg is achieved. If the target MAP cannot be achieved or maintained with 4 L of normal saline boluses, start a norepinephrine infusion at 8 to 12 µg/min and titrate to the target MAP. Additional vasopressor support can be added with fluids and vaspressors, as needed. If the patient is persistently hypotensive, despite standard resuscitative measures, initiate HD. ADH blockade with fomepizole or ethanol is not indicated because this will only prolong the hypotensive and CNS depressant effects of IPA.

Disposition

Due to IPA’s rapid absorption on its onset of action, patients who are stable and alert 6 hours after ingestion are unlikely to develop significant complications and can be monitored until no longer clinically intoxicated for discharge from the ED. Patients with significant inebriation or altered mental status should be admitted as an inpatient or placed in an observation unit for 24 hours. Consult gastroenterology for patients with hemorrhagic gastritis for endoscopy. Consult nephrology for patients with a comatose state or refractory hypotension for HD. Consult the regional poison center (1-800-222-1222) or medical toxicologist to help guide management.

OTHER ALCOHOLS OF CLINICAL SIGNIFICANCE

Diethylene glycol (DEG) is an odorless, viscous, sweet-tasting liquid commonly used as a solvent. It is found in brake fluid, antifreeze, lubricants, wallpaper strippers, and artificial fog solutions. Most exposures to DEG occur in epidemics in which DEG is substituted in pharmaceutical preparations for more expensive glycols. The first epidemic occurred in the United States in the 1930s, with DEG being used as a solvent for suflanilamid, and led to the passing of the 1938 Federal Food, Drug, and Cosmetic Act requiring drug manufactures to demonstrate product safety prior to marketing. Other epidemics include those in South Africa (1969), Spain (1985), Nigeria (1990), Bangladesh (1990–92), Haiti (1996), India (1998), Panama (2006), and Nigeria (2008). DEG toxicity resembles that of EG, with initial GI irritation and CNS depressant effects, and then a resultant metabolic acidosis. ARF without urinary calcium oxalate crystals occurs. Patients who survive ARF, unlike EG, typically require lifelong HD. Neurologic symptoms develop 5 to 10 days postingestion and can include lethargy, cranial neuropathies, peripheral polyneuropathies, and quadripareisis. DEG is metabolized into 2-hydroxyethoxyacetic acid and does not metabolize into EG, as once believed. Management is similar to that of methanol and EG and includes ADH blockade and early HD.

Propylene glycol (PG) is commonly used as a solvent in various pharmaceutical products and in antifreeze and hydraulic fluids. Common xenobiotics that use PG as a solvent include IV pentoytin, lorazepam, diazepam, etomidate, nitroglycerin, phenobarbital, hydralazine, and trimethoprim-sulfamethoxazole. PG is metabolized to lactic acid and can produce a metabolic acidosis. Also, it can contribute to an elevated osmolar gap. Because PG has a short half-life, the osmolar gap rapidly returns to normal once it is discontinued. Underlying renal insufficiency and hepatic dysfunction increase the risk for toxicity. Case reports have noted acute kidney injury from proximal tubular necrosis with PG toxicity. Additionally, PG toxicity can mimic a systemic inflammatory response syndrome and cause a confounding picture, with an elevated osmolar and anion gap triggering exploration for methanol and EG exposure. Approximately 20% of intensive care unit patients on a lorazepam infusion can have some degree of PG toxicity. Treatment typically involves stopping the offending agent, but HD and ADH blockade can be considered for severe acidosis and metabolic abnormalities.
Serum osmolarity is calculated by the following equation:

Calculated osmolarity (mOsm/kg) = 2Na+ + (BUN/2.8) + (glucose/18) + (ethanol/4.6)

The measured osmolar gap is the difference between the measured serum osmolality and calculated serum osmolarity, with a normal range of −15 to +10 mOsm.

The classic finding of an elevated osmolar and anion gap should raise suspicion of methanol or ethylene glycol toxicity but may not be present, depending on the timing of ingestion. Early ingestion has a high osmolar gap without acidosis, and late ingestion has acidosis without an osmolar gap.

A normal osmolar gap does not exclude toxic alcohol ingestion.

Initiate therapy based on clinical suspicion of exposure to methanol or ethylene glycol. Block alcohol dehydrogenase preferably with fomepizole, but ethanol can be used if fomepizole is unavailable.

The presence of acidosis indicates accumulation of the toxic metabolites of methanol (formic acid) and ethylene glycol (glycolic and oxalic acid). Consult nephrology for emergent hemodialysis to correct acid-base disturbances and remove the parent compound and its toxic metabolites.

Severe acidosis is a poor prognostic factor, with high mortality rates in methanol and ethylene glycol ingestions. A comatose state at time of presentation also is associated with a higher mortality outcome.

The main priorities in toxic alcohol exposure are correction of acidosis using bicarbonate solution and hemodialysis, inhibition of the production of toxic metabolites, and elimination of the parent alcohol and its toxic metabolites.

The findings of an elevated osmolar gap with ketonemia or ketonuria and no development of acidosis indicates isopropanol ingestion. Patients can have a prolonged period of inebriation and can be comatose. Alcohol dehydrogenase inhibition is not indicated in these cases.

Hypotension and GI bleeding are poor prognostic factors in isopropanol ingestion.

Diethylene glycol can result in acidosis and renal failure and should be managed similarly to ethylene glycol poisoning with fomepizole and early hemodialysis.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Windshield washer fluid can contain high concentrations of methanol. Methanol itself does not cause toxicity or an anion gap toxicity. Ingestion of ethylene glycol can result in hypocalcemia, which is caused by calcium precipitation with oxalate. Although ethylene glycol ingestion can result in renal failure that can then cause hyperkalemia, it is not associated with QT prolongation. Hypokalemia and hypomagnesemia can both cause QT prolongation; neither is associated with ethylene glycol ingestion.

CHAPTER 141: QUESTIONS & ANSWERS

141.1. A 24-year-old man presents after an intentional methanol ingestion. The patient reports that 1 or 2 hours ago he drank approximately 8 ounces of windshield washer fluid in a suicide attempt. He is not sure of the product name. His only current complaint is slight nausea. His vital signs and physical examination are within normal limits. Serum chemistry reveals the following: sodium, 142 mEq/L, potassium, 4.5 mEq/L, chloride, 110 mEq/L, bicarbonate, 22 mEq/L, blood urea nitrogen (BUN), 18 mg/dL, creatinine, 1.5 mg/dL, and glucose, 111 mg/dL. Serum methanol levels are not obtainable at your hospital. The psychiatry service asks if the patient is medically cleared. Which of the following is the most appropriate response?

A. The patient is cleared; he has a normal anion gap, so no significant methanol ingestion occurred.
B. The patient is cleared; ingestion of 8 ounces is below the toxic level regardless of the concentration.
C. The patient is not cleared; he has an elevated anion gap and needs to receive treatment for methanol toxicity.
D. The patient is not cleared; he has evidence of renal failure and needs to receive treatment for methanol toxicity.
E. The patient is not cleared; not enough time has elapsed from the ingestion to determine if significant toxicity has occurred.

Answer: E. Windshield washer fluid can contain high concentrations of methanol. Methanol itself does not cause toxicity or an anion gap acidosis but its metabolites do, specifically formic acid. It can take 12 to 24 hours for acidosis to develop and even longer if a significant amount of ethanol has also been ingested. This patient should be observed and treated. This patient’s anion gap is 10 mEq/L, which is within normal limits. Ingestion of very small amounts of methanol can be fatal or cause permanent neurologic or ophthalmologic damage. As little as 15 mL of 40% methanol can cause death in adults.

141.2. A 44-year-old woman complains of abdominal pain and headache. Her family reports that the patient drank “something” approximately 8 hours ago in a suicide attempt. The patient is sleepy but arouses with manual stimulation. Her speech is confused, but she follows all simple commands. Her vital signs are blood pressure, 124/82 mm Hg, heart rate, 108 beats/min, respiratory rate, 26 breaths/min, and temperature, 37.0°C (98.6°F). Her physical examination is unremarkable. Her serum chemistry reveals an anion gap of 24 mEq/L. Other laboratory work is pending. Which of the following treatments should be administered initially?

A. Diuresis
B. Hemoperfusion
C. Intravenous flumazenil
D. Intravenous fomepizole
E. Oral activated charcoal

Answer: D. Intravenous fomepizole should be administered. This patient has likely ingested methanol or ethylene glycol, both of which can cause these symptoms, as well as an anion gap metabolic acidosis. The definitive treatment for both ingestions is hemodialysis, which can take some time to arrange. Treatment should be started with fomepizole, even before a definitive diagnosis has been made. Fomepizole and ethanol act by inhibiting the conversion of methanol or ethylene glycol to toxic substances, thereby allowing elimination of the much less toxic original compounds. Diuresis and hemoperfusion are not effective for methanol or ethylene glycol. Flumazenil will reverse the effect of benzodiazepine but should always be used with caution so as not to induce seizure activity. Oral charcoal is not effective for methanol or ethylene glycol, especially after such a long delay.

141.3. A 20-year-old man presents after ingesting antifreeze. His electrocardiogram (ECG) is shown below. Which electrolyte abnormality is most likely responsible for the findings on the ECG?

A. Hypercalcemia
B. Hyperkalemia
C. Hypocalcemia
D. Hypokalemia
E. Hypomagnesemia

Answer: C. Hypocalcemia is a cause of QT prolongation. Ingestion of ethylene glycol can result in hypocalcemia, which is caused by calcium precipitation with oxalate. Although ethylene glycol ingestion can result in renal failure that can then cause hyperkalemia, it is not associated with QT prolongation. Hypokalemia and hypomagnesemia can both cause QT prolongation; neither is associated with ethylene glycol ingestion.
141.4. An otherwise healthy patient presents after a suicidal ethylene glycol ingestion. He is drowsy. His serum pH is 7.1. You have started treatment with fomepizole and have contacted the nephrologist to arrange dialysis. In the meantime, what should be done about the patient’s acidosis?

A. Normal saline should be administered to facilitate clearance of the acid.
B. Nothing should be done; dialysis will correct the acidosis.
C. Nothing should be done; the fomepizole will correct the acidosis.
D. Nothing should be done; the patient is not truly acidotic, but ethylene glycol interferes with the laboratory determination of pH.
E. Sodium bicarbonate should be administered to neutralize the exogenous acid.

Answer: E. Unlike lactic acid, which will be metabolized to bicarbonate, the acidic metabolites of methanol and ethylene glycol cannot be metabolized to bicarbonate and can cause a severe acidosis if not treated. Dialysis will correct the acidosis, but early treatment of the acidosis can reverse some of the adverse effects of methanol or ethylene glycol poisoning. Fomepizole prevents the conversion of methanol or ethylene glycol into toxic metabolites but does nothing to the metabolites already produced. Forced saline diuresis in not beneficial and may increase the incidence of acute respiratory distress syndrome.

141.5. Which of the following is an indication for hemodialysis after methanol or ethylene glycol ingestion?

A. Acidosis
B. Blood level of 10 mg/dL
C. Elevated anion gap
D. Hypokalemia
E. Hypokalemia

Answer: A. Metabolic acidosis, renal compromise, visual symptoms, deterioration despite intensive supportive care, and electrolyte abnormalities unresponsive to conventional therapy are all indications for hemodialysis. Although an anion gap is often associated with metabolic acidosis, an anion gap in and of itself is not an indication for hemodialysis. There is debate about the alcohol levels that indicate the need for hemodialysis. Recommendations have been made to dialyze patients with levels of methanol or ethylene glycol between 25 and 50 mg/dL.

141.6. Which of the following cofactors helps with the elimination of methanol and should be given to patients with methanol poisoning?

A. Folate (vitamin B$_9$)
B. Hydroxocobalamin (vitamin B$_{12}$)
C. Niacin (vitamin B$_3$)
D. Pyridoxine (vitamin B$_6$)
E. Thiamine (vitamin B$_1$)

Answer: A. Folate is a cofactor in the degradation of formic acid to carbon dioxide and water, the final step in the metabolism of methanol. Folinic acid is recommended to be given 50 mg IV every 4 hours to adults with methanol poisoning. Thiamine and pyridoxine are both useful for patients with ethylene glycol poisoning and should be given. Niacin and hydroxocobalamin are antidotes but play no role in treatment for ethanol or ethylene glycol poisoning.

141.7. Which of the following statements comparing the effects of isopropyl alcohol and ethylene glycol is true?

A. Isopropyl alcohol causes less CNS depression and is less toxic than ethylene glycol.
B. Isopropyl alcohol causes less CNS depression and is more toxic than ethylene glycol.
C. Isopropyl alcohol causes more CNS depression and is less toxic than ethylene glycol.
D. Isopropyl alcohol causes more CNS depression and is more toxic than ethylene glycol.
E. Isopropyl alcohol has the same effects as ethylene glycol.

Answer: C. Isopropyl alcohol causes twice the central nervous system (CNS) depression of ethanol, which causes more depression than ethylene glycol. Isopropyl alcohol is metabolized to acetone, which also causes CNS depression but is relatively non-toxic, except in very high doses.

141.8. A patient presents with decreased mental status after drinking some homemade alcohol. Serum chemistry reveals sodium, 140 mEq/L, potassium, 4.5 mEq/L, chloride, 108 mEq/L, bicarbonate, 22 mEq/L, BUN,
Toxic Alcohols

CHAPTER 141

Toxic Alcohols

28 mg/dL, creatinine, 1.0 mg/dL, glucose, 90 mg/dL, and serum osmolality, 320 mOsm/kg. Urinalysis is positive for ketones. Which of the following is the most likely alcohol ingested?

A. Ethanol
B. Ethylene glycol
C. Isopropyl alcohol
D. Methanol
E. On the basis of this information, the patient probably did not ingest an alcohol.

Answer: C. This patient has a normal anion gap of 10 but an elevated osmolal gap of 25. The osmolal gap equals the measured serum osmolarity minus the calculated serum osmolarity. The calculated osmolarity is

\[(\text{Sodium} \times 2) + (\text{BUN}/2.8) + (\text{glucose}/18)\]

In this case, it is 295 mOsm/kg. Ethylene glycol and methanol both cause a double gap or elevated anion and osmolal gaps. Ethanol and isopropyl alcohol generally elevate only the osmolal gap. Isopropyl alcohol ingestion causes more CNS depression than ethanol ingestion and results in ketonemia and ketonuria as it is metabolized to acetone.
As eloquently stated by Paracelsus in the 16th century, “all substances are poisons; there is none which is not a poison. The right dose differentiates a poison from a remedy.”

**PRINCIPLES OF TOXICITY**

Alcohol is the most common recreational drug taken by Americans, and per capita consumption is increasing. Alcohol is the third leading cause of preventable death in the United States; alcoholism permeates all levels of society and is a preventable cause of morbidity and mortality.1 The widespread incidence and disastrous effects of alcoholism are well known to the emergency clinician. Almost all societies that consume alcohol have related health and social problems. The tragic effects of alcohol not only affect the individual drinker but also have far-reaching implications for the family, community, and workplace.

Alcohol consumption is responsible for 3.8% of global mortality, 4.6% of every disability-adjusted life-year (DALY) lost due to premature death, and is projected to take on increasing importance over time.2 Alcohol use and misuse also have social and financial costs, with estimates of the annual economic costs (eg, the costs of health care and lost productivity) to be over $800/person for the entire US population.3 Alcohol contributes to 79,000 deaths and $223.5 billion in societal costs annually in the United States.4 Harmful consequences and risk of disability exist on a continuum (Fig. 142.1).4

At-risk drinking is defined as heavy or problematic alcohol use that may lead to an array of negative consequences, including social, physical, psychological, legal, and financial problems. Across the United States, at least 24% to 31% of emergency department (ED) patients meet National Institute Alcohol Abuse and Alcoholism (NIAAA) criteria for at-risk drinking.5 At-risk drinking is defined as an average of 15 or more standard drinks/week or 5 or more per occasion for men and 8 or more drinks weekly or 4 or more per occasion for women and people older than 65 years.4

The lifetime prevalence of alcohol use disorder (AUD) in the general population is nearly 20% and of dependence is 13%.5 AUD consist of alcohol dependence, alcohol abuse, and dependence or harmful use. These disorders are common in all developed countries and are more prevalent in men than in women, with lower but still substantial rates in developing countries. However, most people with AUD are difficult to identify because they are likely to have jobs and families and to present with general complaints, such as malaise, insomnia, anxiety, sadness, or a range of medical problems. The prevalence of AUD is higher in specialized populations, affecting about 40% of patients presenting to the ED and 59% to 67% of trauma patients.6 In response to the high prevalence of this disease, the American Medical Association has recommended screening patients for alcohol use problems in medical and surgical settings and EDs.5

Alcohol is a central nervous system depressant. Like benzodiazepines, barbiturates, and drugs that have similar action, it rapidly increases the release of γ-aminobutyric acid (GABA) in the brain, and it inhibits postsynaptic N-methyl-D-aspartate glutamate receptor activity.6 Chronic alcohol consumption also affects central α-adrenergic and β-adrenergic receptors and dopamine turnover.7

Animal studies have suggested that in alcohol withdrawal, the balance of the neurotransmitters GABA and glutamate is altered. Decreased synthesis of GABA and increased synthesis of glutamate might be related to withdrawal symptoms experienced on brutal cessation of chronic alcohol intake.8

About 40% to 60% of AUD cases are explained by genes and the rest by environmental association. Polymorphisms in genes for enzymes that metabolize alcohol are generally associated with a lower risk of AUDs because they increase sensitivity to alcohol. One candidate gene and gene product that has been shown to contribute to the risk of drug abuse and addiction-related phenotypes is the mu opioid receptor (MOR; OPRM1 gene).5

**Metabolism of Alcohol**

Ethanol is rapidly absorbed from the stomach and small intestine. It is distributed uniformly to all organ systems, including the placenta. Although 2% to 10% of alcohol is excreted through the lungs, urine, and sweat, most is metabolized to acetaldehyde, primarily by alcohol dehydrogenase (ADH). The oxidation of alcohol is a complex process involving three enzyme systems, all contained in the hepatocyte. Acetaldehyde is then quickly converted to carbon dioxide and water, primarily through aldehyde dehydrogenase (ALDH). The common forms of ADH decrease the alcohol concentration in blood by about 4.5 mmol/L ethanol/hr (the equivalent of about one drink/hr):

\[
\text{Ethanol ADH} \rightarrow \text{Acetaldehyde ADH} \rightarrow \text{Acetyl coenzyme A} \rightarrow \text{CO}_2 + \text{H}_2\text{O}
\]

where NAD is nicotinamide adenine dinucleotide and NADH is reduced nicotinamide adenine dinucleotide.

At least two variations of ADH genes (ADH1B*2 and ADH1C*1) produce a slightly more rapid breakdown of alcohol and therefore potentially faster production of acetaldehyde, which is rapidly metabolized by ALDH2. However, about 40% of Asian people (Japanese, Chinese, and Koreans) have an inactive ALDH2 mutation that results in much higher acetaldehyde levels after drinking than normal. About 10% of people who are homozygous for this gene form cannot drink alcohol without becoming sick and have almost no risk of AUD, whereas those who are heterozygous have a relatively low rate of AUD.

An alternative pathway, the microsomal ethanol-oxidizing system (MEOS), is induced by chronic alcohol exposure. The primary component of the MEOS is the molecule cytochrome P<sub>450</sub> which exists in several variants. The variant most important for alcohol metabolism is cytochrome P<sub>450</sub> 2E1 (CYP2E1). Many effects of alcoholism are produced by the toxic byproducts (hydrogen, acetaldehyde), acceleration of metabolism of other drugs,
and activation of hepatotoxic compounds by these metabolic pathways.

Although the liver is the major site of ethanol metabolism, other tissues contribute to its metabolism. ADH is found in the gastric mucosa, but the gastric metabolism of alcohol is decreased in women and those of Asian descent. This increased bioavailability of ethanol or decreased first-pass metabolism may explain the greater vulnerability of women to acute and chronic complications of alcohol.

Alcohol metabolism has two elimination rates. The alcohol elimination rate approximates zero-order kinetics (constant rate) for lower ethanol levels and first-order kinetics (amount of drug removed over time is proportional to the concentration of the drug) for higher levels, especially in chronic alcoholics; most likely, through induction of the MEOS pathway, the elimination rate is increased at higher blood levels.

The absorption and elimination rates of alcohol vary by individual and depend on many factors—diet, gender, body weight and habitus, speed of consumption, gastric motility, presence of food in the stomach, smoking history, age, whether the person is a chronic alcohol consumer with enzyme induction and high-activity MEOS, advanced cirrhosis, presence of ascites, and state of nourishment. There is enormous variation among patients in the rate of elimination of ethanol from the blood, ranging from 9 to 36 mg/dL per hour in published data. Although the clearance rate may be as high as 36 mg/dL/hr in some chronic drinkers, 20 mg/dL/hr is a reasonable rate to assume in a typical intoxicated ED patient. This holds true for adults, adolescents, and children, whether they are experienced or inexperienced drinkers.

Physiologic effects vary directly with the blood alcohol level (Table 142.1). Diminished fine motor control and impaired judgment appear with alcohol concentrations as low as 20 mg/dL (0.02 mg%), but wide individual variability exists. Chronic alcoholics can exhibit impressive tolerance. The blood alcohol concentration of a person cannot be accurately determined without quantitative testing. More than 50% of the adult population is obviously intoxicated with a level of 150 mg/dL (0.15 mg%). As the ethanol level rises, the patient’s level of consciousness declines, eventually ending in coma. Death is caused by aspiration or respiratory depression.

Alcohol through passive diffusion will be present anywhere there is water in the body. Hence, expired breath alcohol or saliva can be used to obtain a reliable approximation of blood alcohol concentration in a cooperative patient. This value can be used as a rapid screen for alcohol intoxication.

*These effects are for the occasional drinker. Chronic drinkers can function at much higher alcohol concentrations because of tolerance. On the other hand, patients may become comatose with low levels of alcohol in mixed alcohol-drug overdose.

The neurophysiology of alcohol withdrawal is complex and not fully understood. The hallmark of alcohol withdrawal is central...
nervous system (CNS) excitation, with increased cerebrospinal fluid, plasma, and urinary catecholamine levels.

Alcohol withdrawal syndrome (AWS) is a continuum of syndromes that begins after a decrease in the amount of intake of ethanol. AWS is often divided into three sets of symptoms. The first set consists of autonomic hyperactivity, which appears within hours of the last drink and usually peaks within 24 hours. Common presenting characteristics include trembling, sweating, nausea, vomiting, anxiety, and agitation. The second symptom set includes additional neuronal excitation, with epileptiform seizures and global confusion, usually occurring within 24 to 48 hours of abstinence. The third feature set comprises delirium tremens or alcohol withdrawal delirium (AWD), with auditory and visual hallucinations, confusion and disorientation, clouding of consciousness, impaired attention, and pronounced autonomic hyperactivity. The criteria for withdrawal delirium, as described in Box 142.1, are delirium and alcohol withdrawal. Emergency clinicians should be familiar with a commonly used withdrawal rating instrument known as the Clinical Institute Withdrawal Assessment of Alcohol Scale (CIWA-Ar). See Table 142.2.

**Alcohol-Related Seizures**

Among the many medical problems related to alcohol abuse, the differential diagnosis and management of seizures remain among the most challenging and controversial. Patients presenting to the ED with seizures should be questioned about alcohol intake. Of seizure patients presenting to an ED, 20% to 40% will have their seizures related to alcohol use or abuse. Alcohol is a causative factor in 12% to 24% of patients with status epilepticus. In states where alcohol sales are restricted on Sundays, EDs see a spike in alcohol-related seizures on Mondays.

The primary consideration in the initial care of seizure patients who use alcohol is the recognition of treatable, life-threatening causes. These causes include but are not limited to CNS infection, metabolic disorders, and intracranial hemorrhage. Alcohol may act in one of several ways to produce seizures in patients with or without underlying foci—by its partial or absolute withdrawal after a period of chronic intake, by an acute alcohol-related metabolic disorder (e.g., hypoglycemia, hyponatremia), creation of a situation leading to cerebral trauma, precipitation of seizures in patients with idiopathic or post-traumatic epilepsy, or lowering...
of the seizure threshold in patients with prior existing intracerebral disease states. Moreover, alcoholics are more susceptible to other disorders associated with seizures, including neurosyphilis, acquired immunodeficiency syndrome (AIDS), brain abscess, and meningitis.

Alcohol Withdrawal Seizures

Seizures occur 6 to 48 hours after the cessation of drinking. Of patients with seizures, 90% have one to six generalized tonic-clonic seizures; 60% experience multiple seizures within a 6-hour period. The incidence of partial seizures, common with posttraumatic epilepsy, is increased in alcohol withdrawal. The term alcohol withdrawal seizure is reserved for seizures with these characteristics. The term alcohol-related seizure is used to refer to all seizures in the aggregate associated with alcohol use, including this subset of alcohol withdrawal seizure.

Cardiovascular Effects

Acute and chronic ethanol consumption can affect the mechanical function of the heart, produce dysrhythmias, and exacerbate coronary artery disease (CAD). It may alter myocardial function by direct toxic effects, by associated hypertension, or indirectly by altering specific electrolytes. Acute intoxication can decrease cardiac output in alcoholic and nonalcoholic patients with preexisting cardiac disease.

Studies have linked moderate alcohol consumption (two to four drinks/day in men and one or two/day in women) to a protective effect from CAD. Low to moderate alcohol consumption decreases platelet aggregation, raises plasma levels of endogenous tissue plasminogen activator, and lowers insulin resistance.

Studies have suggested that moderate alcohol consumption, through a reduced risk of CAD, may also protect individuals from congestive heart failure. All these beneficial effects are lost in heavy drinkers, in whom chronic alcoholism is associated with hypertension and congestive cardiomyopathy.

Heavy alcohol consumption has a detrimental effect on those with preexisting CAD. It can reduce exercise tolerance, induce coronary vasoconstriction, and raise heart rate and blood pressure. Additive cardiovascular effects of ethanol and nicotine contribute to dysrhythmias and sudden death in patients with CAD. There is an increased incidence of sudden death among heavy drinkers, regardless of concomitant CAD or smoking.

Supraventricular (usually atrial fibrillation) and ventricular (usually transitory ventricular tachycardia) dysrhythmias, labeled holiday heart, have been documented in alcoholic patients who have been drinking heavily. Tachydyssrhythmias as a result of episodic drinking commonly revert to sinus rhythm with abstinence and do not require immediate intervention if the patient is hemodynamically stable.

Pulmonary Effects

Alcohol reduces the mobilization of alveolar macrophages and their bactericidal capacity. Their impairment is greatest in alcoholics with hepatic cirrhosis. There is evidence that chronic alcohol consumption decreases the level of glutathione, promoting inflammation and remodeling of the lung tissue. These effects, along with aspiration, decreased airway sensitivity, concomitant smoking, and malnutrition, probably account for the increased incidence of pneumonia, particularly lobar pneumonia, among alcoholic patients.

The high prevalence of respiratory disease in alcoholics is largely caused by smoking. Alcohol induces bronchospasm in some asthmatics and increases ventricular ectopy and sleep apnea in patients with chronic obstructive pulmonary disease.

Gastrointestinal and Hepatic Effects

Esophagus and Stomach

Alcoholic patients have a higher incidence of esophagitis, gastric cancer, and esophageal carcinoma than that in the general population. Acute alcohol ingestion also decreases lower esophageal sphincter pressure, delays gastric emptying, and disrupts the normal gastric mucosal barrier. Alcohol consumption, because of its inherent toxicity, has been shown to eliminate infection of the gastric mucosa by Helicobacter pylori. Forceful or persistent emesis can lead to a Mallory-Weiss tear or Boerhaave’s syndrome.

Gastrointestinal Bleeding

Alcohol is closely associated with gastrointestinal (GI) bleeding. Causes and contributing factors include Mallory-Weiss tears, esophagitis, esophageal varices, acute and chronic gastritis, thrombocytopenia, portal hypertensive gastropathy, qualitative and quantitative platelet disorders, and prolonged clotting times. Alcohol may exacerbate gastric mucosal damage when it is combined with nonsteroidal antiinflammatory drugs (NSAIDs), but ethanol itself is not a risk factor for peptic ulcer disease. Peptic ulcer disease is the most common cause of bleeding in alcoholic patients with upper GI hemorrhage, as well as in those who do not drink.

Liver Damage

Hepatic damage has been recognized for centuries as the hallmark of chronic alcohol abuse. The activation of the immune system with the production of cytokines such as tumor necrosis factor alpha is one of the earliest events in many types of liver injury. This cascade stimulates Kupffer cells and the production of other cytokines that together enlist inflammatory cells, kill hepatocytes, and initiate healing through fibrogenesis. There is no single test that can be used to diagnose alcoholic liver disease reliably. However, a ratio of aspartate transaminase (AST) to alanine transaminase (ALT) higher than 2 suggests that alcohol is the cause of liver injury. Alcoholic liver disease is the most common liver disorder in the West and, along with hepatitis C, is a leading cause of liver transplantation.

Alcoholic Hepatitis

Alcoholic hepatitis is more serious than fatty infiltration and develops in up to 35% of heavy drinkers. These individuals usually have right upper quadrant pain, a tender enlarged liver, fever, jaundice, leukocytosis, and altered liver function test results. AST levels are usually less than 400 IU/L, and ALT levels are typically less than half the AST level. Alcoholic hepatitis has a range of clinical manifestations, from mildly symptomatic hepatomegaly to fulminant hepatic failure. The severity of the disease can be estimated in the ED by a prolonged prothrombin time/international normalized ratio (INR) or with the use of the Maddrey discriminant factor. The ABIC (age, bilirubin, INR, creatinine) score and model for end-stage liver disease (MELD) are also helpful in predicting mortality in these patients.

Alcoholic Cirrhosis

Cirrhosis is the disruption of the normal architecture of the liver by scarring and regenerating nodules of parenchyma. Alcoholism is the most common cause of cirrhosis in the United States and is responsible for approximately 50% of all cirrhotic deaths. Alcoholic cirrhosis usually requires 10 to 15 years of chronic drinking,
often punctuated by one or more episodes of acute alcoholic hepatitis. The clinical outcome is determined by the development of complications of portal hypertension and by hepatic dysfunction. It is unknown why hepatic damage develops in some alcoholic patients and not in others exposed to identical amounts of alcohol. The disorder was originally described as nutritional cirrhosis, but it has been shown that alcohol, independent of malnutrition, produces the liver damage. Alteration of the normal hepatic architecture by fibrosis and nodule formation may eventually lead to portal hypertension. Portal hypertension may be complicated by ascites and esophageal varices. Although cirrhosis is irreversible, its progression may be halted with abstinence.

No specific medical therapy exists for alcoholic liver disease other than abstinence, proper diet, and management of the subsequent hepatic decompensation (ie, ascites, encephalopathy). A decrease in the amount of alcohol consumed during 1 year is associated with a 60% decrease in mortality.

Pancreatitis and Malabsorption
The association of ethanol with acute and chronic pancreatitis is well established, but the exact pathogenesis is unclear. Hypotheses include reflux of duodenal contents and bile into the pancreatic duct, obstruction by a plug of pancreatic juice rich in proteins, and a direct toxic effect of ethanol.

The diagnosis of alcoholic pancreatitis can be difficult because asymptomatic alcoholics may have an elevated amylase level. Conversely, up to 30% of patients with acute alcoholic pancreatitis have an amylase value within normal limits. The serum lipase level rises after amylase, remains elevated longer, and is a more reliable indicator of alcoholic pancreatitis, especially when it is more than three times normal. Alcohol is the leading cause of chronic pancreatitis.

Diarrhea and impaired intestinal absorption are common problems of the chronic alcoholic. Alcohol increases small intestine transit time and decreases brush border enzyme activity. Thiamine, vitamin B12, amino acids, folic acid, and glucose have impaired absorption in alcoholics. Dietary deficiencies in folic acid and protein, pancreatic insufficiency, abnormal biliary secretion, and direct toxic effects of ethanol on the GI tract contribute to malabsorption. Abstinence and adequate nutrition reverse the diarrhea and much of the malabsorption.

Neurologic Effects
Neuropathy
A symmetric sensorimotor polyneuropathy is common with chronic alcohol abuse, usually in the lower extremities. It is thought to be a combination of nutritional deficiency with thiamine or vitamin B12 deficit and a direct neurotoxic effect of alcohol. Burning pain and paresthesia are common complaints. Findings on physical examination include loss of light touch, decreased pinprick sensation, and reduced lower extremity deep tendon reflexes. Distal muscle weakness is a late finding. The neuropathy may lead to nonhealing ulcers on the feet. Treatment of alcoholic neuropathy is abstinence, adequate diet, and thiamine. Complete recovery is rare.

So-called Saturday night palsy or honeymooner’s syndrome is a wrist drop caused by radial nerve compression. The patient usually has spent the night with his or her arm drooped over the back of a chair, bench, or companion, compressing the radial nerve against the humerus and producing a neurapraxia. Loss of function due to radial nerve neurapraxia usually returns after a few weeks to months.

Wernicke-Korsakoff Syndrome
Although they are similar pathologically and are caused by thiamine deficiency, Wernicke and Korsakoff syndromes are clinically distinct. Wernicke’s encephalopathy, a medical emergency with a mortality rate of 10% to 20%, remains a clinical diagnosis and is often unrecognized. Contemporary criteria require two of these signs—dietary deficiencies, ocular abnormalities (nystagmus is most common), cerebellar dysfunction, and an altered mental state or mild memory impairment. Mental abnormalities include lethargy, inattentiveness, abulia, and impaired memory, progressing without treatment to coma.

Korsakoff’s psychosis or amnesic state, also called alcohol-induced persisting amnestic disorder, is a disorder with recent memory impairment, inability to learn new information or recall previously learned information, apathy, and confabulation. Although it is common, confabulation is not essential for the diagnosis. Whereas 80% of patients with acute Wernicke’s encephalopathy have Korsakoff’s syndrome, age older than 40 years and many years of heavy alcohol use are additional risk factors.

Treatment of Wernicke-Korsakoff syndrome consists of abstinence, adequate diet, and thiamine. The ophthalmoplegia and nystagmus usually have a good response to thiamine within hours to days. The ataxia and mental changes may take days to weeks to improve and usually have a poorer prognosis. Less than 25% of patients show any real recovery, 50% show some recovery, and the remainder show no response, despite adequate thiamine replacement. Because magnesium is a cofactor for this enzyme system, its serum levels should be corrected. Patients with Wernicke’s syndrome require admission and thiamine and magnesium repletion.

Movement Disorders
Alcohol withdrawal is associated with tremor, ataxia, and myoclonus. Acute alcohol consumption ameliorates essential tremor and myoclonus. Persistent tremor is occasionally seen in chronic alcoholism. This alcoholic tremor may persist up to 1 year after abstinence. Although the pathophysiologic mechanism is poorly understood, studies have confirmed that essential tremor and alcoholic tremor are distinct entities.

Alcoholic Cerebellar Degeneration
Characterized by ataxia of the extremities, cerebellar ataxia of alcoholism results in a wide-based stance and uncoordinated gait. Lower extremity involvement predominates, although the arms may rarely be involved. Pathologic changes consist of degeneration of elements in the cerebellum, especially the Purkinje cells. The diagnosis is based on history, physical examination, and findings on magnetic resonance imaging or computed tomography (CT), which shows severe cerebellar atrophy. Treatment consists of abstinence, adequate nutrition, and thiamine.

Infectious Disease
Chronic alcohol abuse causes immunosuppression. Neutropenia may be found in up to 8% of hospitalized alcoholics. Alcohol ingestion prevents the normal delivery (chemotaxis) of polymorphonuclear neutrophils to sites of bacterial infection. Chronic alcohol exposure depresses the development and expression of cell-mediated immunity. This depression may contribute to the high incidence of tuberculosis and head, neck, and upper GI cancers in alcoholics. The suppression of macrophage function by alcohol reduces the reticuloendothelial system’s ability to clear particles. This may contribute to spontaneous bacteremia, spontaneous bacterial peritonitis, and pneumonia. Primary antibody
response to new antigens is also depressed. Malnutrition and liver failure also contribute to an immunocompromised state in the alcoholic.

The most common infection in alcoholism is pneumonia. Associated risk factors for pneumonia in alcoholics include smoking, decreased ciliary function, decreased surfactant production, depressed cough reflex, malnutrition, and poor oral hygiene. Although alcoholic patients may contract a variety of bacterial pneumonias, *Streptococcus pneumoniae* is still the most common organism. Periods of alcoholic stupor with incomplete glottic closure and subsequent aspiration can lead to aspiration pneumonia or lung abscess. *Klebsiella pneumoniae*, classically associated with alcoholism, is currently more common in patients with cytotoxic chemotherapy, hematologic malignant disease, and transplantation than in the chronic alcoholic. In addition, these infections now tend to be nosocomial rather than community-acquired.

**Endocrine Effects**

Alcohol dependence adversely affects many endocrine systems. Peripheral thyroid hormone dysfunction and central hypothalamo-pituitary-thyroid axis deregulation are seen. Male hypogonadism and feminism are seen in chronic male alcoholics. Alcohol's effects on the testes and hypothalamus decrease testosterone production in men. Alcohol may cause impotence by CNS sedation, secondary depression, or decreased testosterone production. Decreased testosterone, increased estrogen (in patients with liver disease), and increased prolactin levels can lead to decreased libido, feminization, and gynecostasia in male alcoholics and to abnormalities in lactation and menstruation in women. In female alcoholics, increased levels of testosterone and estrogen are found. Estrogen replacement therapy may increase hormonal levels threefold and thus increase the risk of cholelithiasis and breast cancer.

**Metabolic Effects**

### Carbohydrates

Alcohol-induced hypoglycemia occurs in 1% to 4% of intoxicated ED patients. It is more frequently seen in chronic alcoholics. Coma, seizures, hemiparesis, and a variety of other neurologic signs have been described in patients presenting with alcohol-induced hypoglycemia. Starvation, depletion of liver glycogen stores, decreased plasma cortisol levels, impaired release of growth hormone, and inhibition of gluconeogenesis contribute to this phenomenon.

Hyperglycemia and diabetes may be found in chronic alcoholism. Alcohol abuse can lead to chronic pancreatitis, resulting in underproduction of insulin by the damaged pancreatic cells. Alcohol also impairs peripheral glucose utilization, causing a relative insulin resistance (similar to type 2 diabetes). In diabetic patients, alcohol can induce hypoglycemia and also mask the signs of hypoglycemia.

### Lipids

A reversible hypertriglyceridemia occurs in many chronic alcoholics. Ethanol increases hepatic synthesis of triglycerides. Abstinence is necessary to reduce elevated triglyceride levels. Except for its relationship to fatty infiltration of the liver, the clinical significance of this hyperlipidemia is unknown.

### Electrolytes

Ethanol has numerous effects on electrolytes and mineral metabolism, as summarized in Table 142.3. Hyponatremia and hypokalemia are common in active drinkers. Vomiting, diarrhea, magnesium depletion, malnutrition, and metabolic alkalosis contribute to these abnormalities.

↑, Into plasma; ↓, out of plasma.
Alcoholism is the most common cause of severe magnesium deficiency in adult outpatients. Magnesium deficiency is seen in 30% of alcoholics as a result of malabsorption, malnutrition, diarrhea, vomiting, and increased urinary losses. Oral magnesium supplementation in chronic alcoholics improves liver function test findings, electrolyte balance, and muscle strength. Multivitamin preparations may be considered for chronic malnutrition. Although their clinical benefit is not proved, they carry no significant risk or cost.

Hypocalcemia is common in alcoholic patients with magnesium depletion. The mechanism is related to diminished parathyroid hormone secretion, decreased tissue responsiveness to parathyroid hormone, decreased vitamin D metabolism, and decreased calcium release from bone, independent of parathyroid hormone. Correction of magnesium depletion is necessary to restore calcium to normal levels. Hypocalcemia, pancreatitis, or vitamin D deficiency also contribute to low serum calcium levels or low total body stores of calcium in alcoholic patients.

Hyponatremia is found in 30% to 50% of hospitalized patients with alcoholism. Phosphorus depletion results from malnutrition, vomiting, respiratory alkalosis, diarrhea, enhanced release of calcitonin, phosphate-binding antacids, and urinary loss (related to vitamin D deficiency and secondary hyperparathyroidism). Hypophosphatemic patients often have low magnesium levels. Rehydration, carbohydrate repletion, and parenteral alimentation further exacerbate phosphorus depletion. Glucose bolus and infusion have been shown to produce a significant fall in serum inorganic phosphate levels. Severe hypophosphatemia (<1 mg/dL) has been associated with acute respiratory failure, myocardial depression, dysfunction of erythrocytes, leukocytes, and platelets, CNS irritability, and rhabdomyolysis.

Although chronic alcoholics requiring admission often have potassium, magnesium, and phosphate depletion, empirical treatment with potassium and phosphate is discouraged. Serum levels and renal function should be determined. Unintended hyperkalemia and hyperphosphatemia can produce significant morbidity, and phosphate infusion exacerbates hypocalcemia, if present. Because most magnesium is intracellular, a normal serum magnesium level does not rule out decreased total body magnesium stores. If the serum level is normal, total body levels may still be low. As long as renal function is adequate, empirical magnesium treatment can be considered. Abstinence and a proper diet resolve electrolyte and nutritional deficiencies in the ambulatory alcoholic patient who is healthy enough to be treated as an outpatient.

Alcoholic Ketaacidosis

Alcoholic ketoacidosis occurs most frequently in severe chronic alcoholics who have had a recent binge followed 1 to 3 days later by protracted vomiting, decreased food intake, dehydration, and abstinence. Nausea, vomiting, and abdominal pain are common presenting complaints. These patients have tachypnea, dehydration, ketonuria, and little or no glucosuria. Serum glucose levels are usually less than 200 mg/dL. Normal blood pH may be found despite ketonemia because of coexisting respiratory alkalosis and metabolic alkalosis.

The exact mechanism responsible for the increase in ketone bodies is unclear. Acute starvation superimposed on chronic malnutrition, as well as release of an alcohol-induced block in ketogenesis, allowing marked ketosis, may explain the disorder. An increased ratio of NADH to NAD in the alcoholic predisposes to the accumulation of β-hydroxybutyrate and the inhibition of gluconeogenesis, which may underlie the common occurrence of hypoglycemia in alcoholic ketoacidosis.

The alcoholic patient with metabolic acidosis presents an interesting dilemma because most of these patients have an increased anion gap acidosis. Glucosuria may suggest diabetes, crystalluria can be seen in ethylene glycol poisoning, low specific gravity, proteinuria, and casts can be seen in renal failure, leukocytes and bacteria are present with urosepsis, and significant ketones in an otherwise normal urine may indicate starvation or alcoholic ketosis. Elevated levels or a very high osmolar gap (>25 mOsm/kg) is specific for methanol or ethylene glycol ingestion.

Treatment of alcoholic ketosis consists of the administration of normal saline, glucose, and thiamine and correction of hypokalemia. This can be accomplished with 5% dextrose in normal saline and 30 mEq of potassium chloride or 30 mEq of oral potassium. If no serious complicating illness is present, the ketosis is reversed in 12 to 24 hours with this treatment.

Hematologic Effects

The alcoholic presents with myriad hematologic abnormalities. The direct toxic effect of ethanol and its metabolites, secondary nutritional deficiency, and hepatic disease, individually or in combination, affect red blood cells, white blood cells, platelets, hemostasis, and the immune system. Macrocystosis is the most common hematologic manifestation of the chronic alcoholic. It may be caused by folate deficiency, reticuloysis (the younger reticulocytes are larger), liver disease (producing an abnormal lipid coating of the red blood cell membrane), or vitamin B12 deficiency. The most common condition is idiopathic macrocytosis of alcoholism.

Anemia

Several mechanisms cause anemia, which is common in the alcoholic. Megaloblastic anemia resulting from folate deficiency is the most common anemia in alcoholics. The mean corpuscular volume (MCV) is typically increased but may be normal when iron deficiency coexists. Malnutrition, inability of the cirrhotic liver to store folate, excessive urinary loss, and malabsorption decrease folate stores. Alcohol accelerates the development of megaloblastic anemia in individuals with depleted folate stores (MCV > 100 fl) by a less clearly defined mechanism.

Iron deficiency anemia is common and is usually a result of blood loss from the GI tract. With iron deficiency anemia, the serum iron level is decreased, total serum iron-binding capacity is elevated, and serum ferritin level is decreased. Alcoholics frequently have chronic inflammatory diseases such as endocarditis, tuberculosis, empyema, lung abscess, malignant disease, and hepatic disease. These illnesses can produce the anemia of chronic disease, a mild microcytic or normocytic anemia in which the serum iron is low but, in contrast to iron deficiency, the total serum iron-binding capacity is low or low-normal, and the serum ferritin level is increased.

Ethanol also has a direct toxic effect on erythropoiesis. Bone marrow biopsies reveal vacuolization of erythroid precursors, resulting in decreased reticuloysis and a reversible sideroblastic anemia. Sideroblastic anemia, which is usually seen in the presence of malnutrition with pyridoxine deficiency and folate deficiency, occurs in 25% to 30% of anemic alcoholics.

Leukocyte Abnormalities

Leukopenia is common in the alcoholic patient and has several possible causes. Sepsis, folate deficiency, and hypersplenism all lead to a decreased white blood cell count. Alcohol has a direct toxic effect on white blood cell production in the bone marrow. Granulocyte mobilization (chemotaxis) and adherence are also impaired, resulting in a decreased inflammatory response.
Platelet Disorders

Thrombocytopenia can occur with folate deficiency, marrow suppression, sepsis, disseminated intravascular coagulation, or splenic sequestration. The direct toxic effects of alcohol decrease measured survival time and impair production of platelets in the bone marrow, but marrow toxicity will rarely reduce the platelet count below 30,000/mm³. Qualitative platelet function is also impaired. Binge drinking is associated with a reactive thrombocytosis potentially responsible for acute stroke and sudden death.

Hemostasis

Alcoholic patients have a bleeding diathesis for many reasons, including thrombocytopenia, qualitative platelet disorders, deficient production of hepatic clotting factors, GI variceal formation, and vitamin K deficiency. A complete blood count, peripheral smear, platelet count, reticulocyte count, thrombin time, prothrombin time and INR, and partial thromboplastin time help evaluate episodes of significant bleeding. Bleeding associated with coagulation abnormalities may require fresh-frozen plasma for the immediate correction of coagulation factor depletion; vitamin K (10 mg IV) takes 6 to 10 hours to reverse the vitamin K–dependent factors II, VII, IX, and X. Because of poor diet and impaired hepatobiliary function, alcoholics may have insufficient vitamin K storage and benefit from vitamin K delivery. However, alcoholic patients with profound liver failure are unable to produce the precoagulation factors II, VII, IX, X, and IV, so vitamin K therapy is futile. Platelet transfusions should be started in the ED for adult patients with active bleeding when the platelet count is less than 50,000/mm³.

Oncologic Effects

Worldwide, 389,000 annual cases of cancer representing 3.6% of all cancers are alcohol-related. Although alcohol itself is not carcinogenic, its metabolite, acetaldehyde, has emerged as an important contributor; it can form stable DNA adducts, trigger mutations in tumor suppressors and oncogenes, and interfere with DNA repair. Smoking certainly has an additional role as a cause of neoplasia and is difficult to isolate in these studies.

Chronic alcohol use is associated with an increased incidence of upper alimentary and respiratory tract cancers, with a clear dose-response relationship. Specifically, alcohol increases the risk of cancer of the mouth, pharynx, larynx, lung, esophagus, liver, and pancreas. Chronic hepatitis B infection may sensitize the liver to alcohol, producing hepatocellular carcinoma. Women who drink two to five drinks/day have a relative risk of 1.41 for invasive breast cancer compared with nondrinkers. There is also a significant increase in endometrial cancer risk among postmenopausal women who consume more than two alcoholic drinks/day. Moderate alcohol consumption leads to an increased risk of colorectal and prostate cancer.

Psychiatric Effects

Of alcohol-dependent adults, 45% are diagnosed with one or more additional psychiatric conditions during their lifetime. Of alcoholic men admitted to a psychiatric ward, approximately 40% have another psychiatric disorder unrelated to substance abuse—in particular, antisocial personality disorder, schizophrenia, mood disorders, and anxiety disorders.

Depression and antisocial personality are the two most common psychiatric disorders that correlate with alcoholism, with a prevalence of 30% to 60% in most studies. Chronic alcohol use can produce an imbalance in the serotoninergic system. This imbalance may lead to increased anxiety, aggression, and depression. Interestingly, behavior is more strongly linked to depression than to alcohol dependence. Secondary depression may be caused by alcoholism, or the primary affective disorder may be present with secondary alcoholism. Mild depressive symptoms are also common in alcohol withdrawal. Antisocial individuals are at high risk for alcoholism and drug dependence, although an unstable, unhappy childhood environment appears to be more important than alcohol to the development of sociopathy. Alcohol increases the lifetime risk of suicide, with 17% of all alcoholics eventually dying by suicide. Alcoholism, major depression, and antisocial personality all predispose to suicide, and interaction among the three is particularly dangerous, but the acute risk on any particular day is difficult to assess.

Toxicologic Effects

Alcohol has long been known to have additive or even synergistic effects with several drugs. Acute intoxication decreases the rate of drug metabolism, which is at least partially explained by competition for the same enzymatic process in the liver. When cocaine and ethanol are taken concomitantly, the unique metabolite, cocaethylene, is a neurologically active compound that is significantly more toxic than cocaine to the heart, liver, and brain and more addicting and more lethal than cocaine alone. Cocaethylene produces a higher incidence of confusion, lower mean Glasgow Coma Scale (GCS) scores, a higher incidence of violent trauma and more often requires endotracheal intubation. Hemodynamically, these patients demonstrate an elevated heart rate (1.5–5 times normal) and higher blood pressure than with either drug alone. Sudden death is increased up to 25-fold above that associated with the use of cocaine alone. Plasma levels of cocaine in this combined group were higher than in those who used cocaine alone.

Ethanol increases aspirin-induced prolongation of bleeding time and reduces the metabolism of warfarin, leading to increased anticoagulant effects. There is an increased risk of upper GI bleeding when alcohol is combined with NSAIDs. This may be the most dangerous additive or synergistic effect of alcohol.

Disulfiram and Similar Reactions

Most patients pretreated with disulfiram (Antabuse) who then consume even small amounts of alcohol experience an extremely unpleasant reaction. These patients have a hypersensitivity to ethanol and experience a direct response within 15 minutes, lasting 30 minutes to several hours. The reaction consists of skin flushing on the head that spreads to the trunk, along with nausea, vomiting, headache, chest and abdominal discomfort, diaphoresis, vertigo, palpitations, and confusion. A severe reaction may produce hypotension, seizures, and dysrhythmias. The disulfiram-ethanol reaction is thought to occur by the accumulation of acetaldehyde secondary to inhibition of the aldehyde dehydrogenase enzyme, which may be deficient in many Asians, or another unknown toxic factor. This incapacitating reaction has been used to discourage chronic alcohol ingestion. Treatment for disulfiram
reaction is usually just observation, an antieptic for symptoms, and intravenous (IV) fluids.

Profound hypoglycemia can occur when alcohol and oral hypoglycemic agents are combined. Patients taking metformin may have an increased risk for the development of lactic acidosis when it is combined with heavy drinking. A disulfiram–ethanol–like reaction has been described with many hypoglycemic agents.

Other Considerations

Patient Groups Affected

Adolescents. Alcohol is a common drug of abuse among adolescents and young adults. It is estimated that at least 50% of adolescents 12 to 20 years old have imbibed alcohol during any 30-day period. Alcohol is often associated with the three leading causes of death among youth—unintentional injury, homicide, and suicide.

Adolescent drinking is associated with many negative consequences, including deleterious effects on neurocognitive and hormonal development and cognitive and emotional abilities. Social conflicts, delinquency, and problems of academic adjustment are often associated with repeated episodes of heavy drinking, which also put youth at risk for the chronicization of problematic substance use patterns into adulthood.

Older Patients. Unhealthy drinking is found in up to 15% of older ED patients (>65 years). It has been estimated that 50% of older people drink alcohol, and 2% to 4% meet the criteria for alcohol abuse or dependence. Common screening tests (eg, the CAGE questionnaire) tend to be less sensitive in this age group. Alcohol may exacerbate underlying disease by masking anginal chest pain, worsening hypertension, and inducing dysrhythmias. However, older adults who consume low to moderate levels of alcohol may have a decreased risk for the development of dementia and heart failure. More than 90% of people aged 65 years or older use more than one prescribed medication. Aging alters GI absorption, lowers volume of distribution, diminishes homeostatic responses, and reduces renal and hepatic function. Older adults also demonstrate increased end-organ sensitivity, particularly involving the CNS, with concomitant drug use increasing their risk for alcohol and drug interactions.

Older patients are more likely to have neuropsychiatric complications of alcoholism, such as sleep problems, anxiety, depression, and dementia. Alcohol is involved in one third of suicides in older adults. Older subjects also perform less well than younger subjects on tests of perception and attention at all blood alcohol levels. This may result in an increased risk of fractures from falling and osteoporosis. However, evidence has suggested that compared with abstinence, consumption of up to one drink/day is associated with a decreased risk of osteoporotic hip fracture, and there is a beneficial effect of moderate alcohol consumption on bone density.

Pregnant Women. Many scientific reports confirm alcohol’s teratogenic effects. According to the National Institute on Drug Abuse, nearly 20% of all children born in the United States have been exposed to alcohol during gestation. Pregnant women who report the use of any alcohol, binge drinking, or frequent drinking are more likely to be older than 30 years, employed, and unmarried.

Fetal alcohol syndrome is characterized by a triad of CNS defects, including mild to moderate mental retardation, dysmorphology, involving mostly facial structures, and growth deficiencies, usually consisting of short stature and microcephaly. Fetal alcohol syndrome is now considered the most common identifiable source of mental retardation. Children exposed to prenatal alcohol exhibit increased activity levels, cognitive and attention deficits, perseverative behavior, and language and motor problems, which persist into adulthood.

Ethanol rapidly diffuses across the placenta and is distributed to all fetal tissue, with a predilection for gray matter. Although infants of mothers who drink heavily have the poorest outcome, children of mothers who consume only two or three alcoholic drinks/day also display abnormalities. Even in the absence of growth retardation or congenital abnormalities, children born to women who consume excessive alcohol during pregnancy appear to be at increased risk for attention deficit disorders. These findings are referred to as fetal alcohol effects.

Whereas there is no known safe amount of alcohol consumption during pregnancy, an average of less than one drink/day in early or late pregnancy showed no measurable impact on a child’s learning or cognitive functioning in a cohort study of more than 5000 patients observed for 14 years. Adverse outcomes in this study were associated with an average of more than one drink/day, binge drinking, and consumption of alcohol later in pregnancy. The American Academy of Pediatrics recommends abstinence from alcohol for women who are pregnant or who are planning a pregnancy.

Trauma

The single greatest contributor to alcohol-related mortality in the United States is unintentional injury, accounting for approximately 26,000 deaths/year. The importance of alcohol misuse as a precursor to serious injury is widely accepted enough that the American College of Surgeons Committee on Trauma requires screening for problem drinking for designation at a level I or II trauma center. In addition, level I trauma centers must provide an intervention for identified problem drinkers. Alcohol and trauma are inextricably linked. Independently, the tragic effects of each are numerous; in combination, they are staggering. Injury is a leading cause of death in those between the ages of 1 and 44 years, accounting for more than 50 million injuries/year. In the United States, alcohol is the major risk factor for virtually all categories of intentional and unintentional injury. In addition to increasing the frequency and severity of injury, alcohol significantly complicates management of the trauma victim. Alcohol intoxication often complicates the initial assessment of injury severity, resulting in an increased need for invasive diagnostic and therapeutic procedures (eg, intubation, CT, intracranial pressure monitoring).

Alcohol may diminish the patient’s capacity to respond to hemorrhagic shock by altering hemodynamic effects and the acid-base balance. Volume depletion as a result of the diuretic effect of alcohol or vomiting can impair the reserve of the intoxicated trauma patient. Peripheral vasodilation caused by alcohol may contribute to hypotension and hypothermia. Although these effects may be minimal, they underscore the need for early and adequate fluid resuscitation in these patients. Intoxicated patients with severe nonneurologic trauma may have lower blood pressures and carbon dioxide levels, indicative of a compensatory hyperventilation, on hospital arrival compared with sober patients. More important, a poorly understood cardiac depressant effect also increases the depth of shock and volume requirements for resuscitation. Alcohol-induced skin vasodilation may be accompanied by an increase in skeletal muscle, mesenteric, and renal bed constriction and left ventricular stroke work. Thus, the overall effect on systemic vascular resistance and blood pressure may be balanced.

Intoxication renders the signs and symptoms of intra-abdominal and retroperitoneal injury less reliable than usual. If the risk of an intra-abdominal injury exists, further evaluation (eg, ultrasonography, CT) should be considered.
Alcohol intoxication predisposes to abdominal wall laxity and therefore less protection from blunt trauma. These patients are also likely to have full stomachs, increasing the risk of gastric injury after trauma and predisposing to vomiting and aspiration, especially during airway management. The fatty liver changes of alcoholism can result in hepatomegaly. Portal hypertension in alcoholics may produce splenomegaly. These organs can become more vulnerable to the effects of trauma because of their enlarged size, protrusion beneath the protection of the ribs, and increased intracapsular pressure.

No consensus exists on the indications for an emergency CT scan in patients with minor head injury (eg, loss of consciousness, posttraumatic amnesia, GCS score of 14–15, normal findings on neurologic examination). One disturbing prospective study has found that the GCS score and 1 hour of observation were unable to predict abnormal head CT scans in intoxicated patients with minor head trauma. Patients with signs of head trauma and focal or generalized seizures need an urgent CT scan. CT scans of the head should be performed for any patient with deteriorating mental status, focal neurologic findings, new-onset seizures, even without obvious signs of history of trauma, failure to improve over time, or mental status changes out of proportion to the degree of intoxication.

**Alcohol Withdrawal Syndrome**

**Clinical Features**

The severity of signs and symptoms of alcohol withdrawal syndrome depends on the dose and duration of ethanol consumption. The withdrawal syndrome may occur any time after the blood alcohol level starts to fall. Therefore, only a reduction, not the abrupt cessation, of ethanol intake may result in withdrawal.

Minor alcohol withdrawal occurs as early as 6 hours after cessation of or significant decrease in alcohol intake and usually peaks at 24 to 36 hours. It is characterized by mild autonomic hyperactivity—nausea, anorexia, coarse tremor, tachycardia, hypertension, hyperreflexia, sleep disturbances (eg, insomnia, vivid dreams), and anxiety.

Major alcohol withdrawal occurs after more than 24 hours and usually peaks at 50 hours after cessation of or significant decrease in alcohol intake but occasionally takes up to 5 days to be manifested after the decline or termination of drinking. The syndrome is characterized by pronounced anxiety, insomnia, irritability, tremor, anorexia, tachycardia, hyperreflexia, hypertension, fever, decreased seizure threshold, auditory and, more commonly visual hallucinations, and finally delirium.

Delirium tremens is a life-threatening manifestation of alcohol withdrawal and consists of gross tremor, frightening visual hallucinations, profound confusion, agitation, and a hyperadrenergic syndrome characterized by a temperature above 101°F (≈38.5°C), blood pressure higher than 140/90 mm Hg, and tachycardia. It seldom appears before the third postabstinence day. Only 5% of patients hospitalized for alcohol withdrawal have delirium tremens.

**DIFFERENTIAL DIAGNOSIS**

Acute alcohol intoxication is a diagnosis of exclusion. Before it is assumed that a patient’s behavior is caused only by alcohol, other conditions should be considered, particularly co-ingestants, head trauma, and infection. Hypoglycemia, hypoxia, carbon dioxide narcosis, mixed alcohol-drug overdose, ethylene glycol poisoning, isopropanol or methanol poisoning, hepatic encephalopathy, psychosis, severe vertigo, postictal state, and psychomotor seizures can be manifested in a manner similar to that of ethanol intoxication.

Alcohol withdrawal syndrome can initially be confused with acute schizophrenia, encephalitis, drug-induced psychosis, thyroid-toxicosis, anticholinergic poisoning, and withdrawal from other drugs of the sedative-hypnotic type. It may be difficult to differentiate between alcohol withdrawal and alcohol-induced hypoglycemia.

Signs of alcohol withdrawal usually begin 6 to 24 hours after a decrease in the patient’s usual intake of alcohol. If patients manifest withdrawal 3 to 4 days or more after their last drink, drugs with a longer half-life should be considered. Barbiturate and benzodiazepine withdrawal syndromes usually progress more slowly, with a higher frequency of seizures later (7 days vs. 2 days), and status epilepticus is more common than with alcohol withdrawal.

**DIAGNOSTIC TESTING**

Determination of a blood alcohol level is not routinely necessary in caring for the intoxicated patient when there is clear evidence of alcohol intake (eg, confirmation by the patient). When mental status is sufficiently altered that a good history cannot be obtained, there is evidence of head trauma, or the patient fails to improve (detoxify) as expected, determine the serum alcohol level or measure the alcohol level by breathalyzer. If the degree of obtundation is not commensurate with the measured (or breathalyzed) level, and other laboratory test results (eg, toxicity screen, electrolyte levels) do not explain the altered mental status, a head CT scan is indicated. Adequate history from paramedics, patient, and family, serial physical examinations (especially mental status), and bedside testing, such as glucose level and oximetry, can help clarify the clinical situation and guide testing.

Blood tests can be useful if the history is in doubt and can also help patients recognize that alcohol has adversely affected their health. Tests of liver function that measure AST and ALT levels can identify heavy drinking and AUDs with sensitivities of 25% to 45% and specificities as high as 90%. A ratio of AST to ALT higher than 2, especially if concentrations of these enzymes do not exceed 400 units/L, suggests alcoholic hepatitis (Table 142.4).

**Laboratory Tests**

In the apparently intoxicated patient with altered mental status, the serum glucose level, usually as a point of care test, should be measured to assess for hypoglycemia. In the alcoholic patient, electrolyte levels should be determined to look for hypomagnesemia, hypophosphatemia, hyponatremia, and acidemia. A complete blood count is obtained to evaluate for anemia, leukopenia, and thrombocytopenia and a serum lipase level to evaluate for pancreatitis if the patient has severe upper abdominal pain or tenderness, especially if accompanied by vomiting. Liver function tests are followed in a serial manner in cases of alcoholic hepatitis. An electrocardiogram (ECG) is indicated for tachyarrhythmias or chest pain (eg, holiday heart, acute ischemia). A CT scan of the head or cervical spine may be indicated if head trauma or seizures are suspected or confirmed or if the patient’s mental status does not clear in step with the metabolism of alcohol. A chest radiograph is obtained to rule out cardiomyopathy or infectious pneumonia.

**Alcohol Screening Questionnaires**

Detection of risky drinking behaviors can be through clinical history or the administration of short alcohol screening tools in the ED setting, such as the Alcohol Use Disorders Identification Test (AUDIT), Fast Alcohol Screening Test (FAST), Paddington alcohol test (PAT), and CAGE questionnaires. Other questionnaires include the rapid alcohol problem screen (RAPS-4) and TWEAK (tolerance, worried, eye opener, amnesia, K [cut down]).
The objectives of these screening tools vary; AUDIT and FAST are focused on the detection of recent hazardous or harmful alcohol consumption and associated problems, whereas CAGE is designed to detect lifetime alcohol dependence. The most sensitive screening tool appears to be FAST (93%–94%), which has a specificity of 86% to 88% and positive predicted value of 86% to 87%. Although FAST appears to be the best for accurately identifying alcohol misuse in ED patients, it was assessed as a universal screening tool and may not be feasible—in regard to time or cost—to screen all who present to this service. In contrast, PAT has been developed to be used on a select population in the ED and has already been shown to be cost-effective.14

As part of the initial assessment and in alignment with national recommendations, computerized screening programs could be used as an effective method for detecting at-risk alcohol use in ED patients. Identification of AUD and brief advice in the ED can be an effective and cost-effective method to reduce levels of alcohol consumption and alcohol-related harm.15

### MANAGEMENT CONSIDERATIONS

Comatose or stuporous patients may require intubation. If the bedside glucose level identifies hypoglycemia, IV glucose, as D5W or an infusion of D10W, is indicated. Patients with evidence of poor nutrition should receive naloxone, 0.4 to 2.0 mg IV, before or early during administration of glucose to prevent Wernicke-Korsakoff syndrome. If an opioid overdose is suspected, IV naloxone, 0.8 mg, may be diagnostic and therapeutic. Because magnesium is a necessary cofactor for thiamine metabolism, consider administering magnesium, 2g IV. When possible, hypoglycemia should be documented before the empirical administration of glucose. With the airway maintained and respirations supported, the patient’s liver eventually metabolizes the alcohol, and most patients recover.

Intoxicated patients who do not appear capable of appropriate decision making require evaluation and treatment in the ED, regardless of their willingness to cooperate. At the least, it is incumbent on the emergency clinician to establish that the patient understands the nature of the problem, whether intoxication alone or intoxication in the context of acute illness or injury, and is capable of making reasoned and responsible decisions about care. Inappropriate discharge and failure to diagnose are two common areas of liability in treatment of the alcohol-dependent patient. The theoretic liability for detention by reasonable restraint is less than the potential liability for injury sustained by the intoxicated patient or an innocent bystander after premature discharge. Discharge can be considered when a patient is clinically sober enough to be able to dress, walk, make reasonable decisions, and function independently, as judged and well documented by the treating emergency clinician. When possible, it is ideal to have another sober adult who is willing to take responsibility for and remain with the patient for the next 24 to 48 hours.

### Alcohol Withdrawal Syndrome

Family, friends, bystanders, or paramedics often give more reliable historical data than the patient does. Accurate vital signs are essential; this may require a rectal temperature. Hyperthermia, hypothermia, tachypnea, or tachycardia may suggest serious disorders that often accompany the alcohol-dependent patient. These disorders should be considered during the initial assessment.

A rapid and thorough examination should be performed, with attention to the level of consciousness, signs of hepatic failure, or coagulopathy. Signs of trauma are sought, such as subcutaneous emphysema, ecchymosis, subconjunctival hemorrhage, hemothympanum, and Battle’s sign, and palpation is done for occult injuries. The neurologic examination should search for focal

findings, including central facial nerve palsy, hemiparesis, and asymmetry of pupillary response.

The alcohol withdrawal syndrome should be promptly recognized and treated. The CIWA-Ar is a validated tool for symptom-based prescribing of chlordiazepoxide for alcohol withdrawal and is an alternative to traditional fixed-dose regimens, which may prolong length of stay for up to 5 days. Scores on the CIWA-Ar range from 0 to 67; scores lower than 8 indicate mild withdrawal symptoms that rarely require the use of medications, scores from 8 to 15 indicate moderate withdrawal symptoms that are likely to respond to moderate doses of benzodiazepines, and scores higher than 15 indicate severe syndromes that require close monitoring to avoid seizures and alcohol withdrawal delirium (delirium tremens).

In combination with appropriate chemical sedation, detention by reasonable restraint may be an option to prevent potential injury that patients may inflict on themselves or hospital staff. These appropriate measures need to be instituted; decision-challenged patients should not be permitted to sign an Against Medical Advice Form and be discharged.

**Pharmacologic Treatment**

Patients suffering from alcohol withdrawal should receive pharmacologic intervention along with supportive care. The ideal drug for alcohol withdrawal should have a rapid onset, wide margin of safety, metabolism not dependent on liver function, and limited abuse potential. Although no one drug class fits all these requirements, benzodiazepines are clearly the mainstay of treatment.

**Benzodiazepines.** The benzodiazepines have superior anticonvulsant activity, have the least respiratory and cardiac depressive effects of all the CNS depressants, and can be given parenterally to the uncooperative patient. By interacting with receptors linked to the GABA-associated chloride ion channel, benzodiazepines substitute for the withdrawal of the GABA-potentiating effect of alcohol and abate withdrawal signs and symptoms. Numerous benzodiazepines have been studied, but there is no evidence of the clear superiority of any one benzodiazepine.

Lorazepam has good bioavailability with the oral, intramuscular, and IV routes. It is rapidly and completely absorbed from intramuscular sites in agitated patients with no IV access. The half-life of lorazepam is intermediate (7–14 hours), and it reaches a steady state in 36 to 48 hours, without active metabolites. Excessive sedation, confusion, and ataxia are potential complications of all benzodiazepines with prolonged half-lives. Lorazepam is metabolized (conjugated) in the liver, yielding inactive products. Although the half-life of lorazepam increases in patients with cirrhosis or liver failure, it is much shorter than the increase with chlordiazepoxide. The elimination of lorazepam is only minimally altered in patients with renal failure and in older adults. Lorazepam may be given IV in a dose of 1 to 4 mg, depending on the severity of the withdrawal. Dosing can be repeated at 5- to 15-minute intervals for patients in severe withdrawal. Although it is not ideal, an intramuscular dose of 1 to 4 mg can be used every 30 to 60 minutes until the patient is calm and then every hour, as needed, for light somnolence. The oral schedule for moderate withdrawal is 6 mg/day in three divided doses, tapering the amount by 1 to 2 mg/day during 4 to 6 days.

As one dosing regimen, diazepam, 5 mg IV every 5 to 10 minutes (2.5 mg/min), can be given in major withdrawal until the patient is calm. The dose can be repeated in 5 to 10 minutes. If the second dose of 5 mg is not working, consider 10 mg for the third and fourth doses every 5 to 10 minutes. If this is not effective, consider 20 mg for the fifth and subsequent dose until adequate sedation has been obtained.

In patients who do not have a response to high doses of benzodiazepines (especially patients who are intubated), propofol may be administered (eg, 0.3 to 1.25 mg/kg of body weight, up to 4 mg/kg/hr, for up to 48 hours).

**Butyrophenones.** Haloperidol, a dopamine antagonist, can be considered in patients with major alcohol withdrawal or delirium tremens not responding to IV benzodiazepines. Haloperidol has little effect on myocardial function or respiratory drive, and its safety and efficacy by the IV, intramuscular, or oral route in the ED have been established. Haloperidol has no anticonvulsant properties; however, extrapyramidal effects may be seen. Caution should be used in patients who may be susceptible to a prolonged QTc interval. Droperidol has effects similar to those of haloperidol. Despite the 2001 US Food and Drug Administration (FDA) black box warning for QTc interval prolongation and torsades de pointes after droperidol use, droperidol remains a relatively safe and effective treatment for agitated patients.

**Other Agents.** Patients being treated for major alcohol withdrawal may be given thiamine (100 mg IV) and magnesium (2 g IV). Although magnesium sulfate does not decrease the severity of withdrawal symptoms, incidence of delirium, or seizures, it carries no significant risk with adequate renal function.

If volume depletion is present, it can be corrected with normal saline. Reversal of electrolyte and metabolic disorders (eg, hypomagnesemia, hypophosphatemia, hypokalemia, acidosis) benefits the patient but does not abate the withdrawal syndrome.

**Neurologic Examination**

**Normal Examination**

**New-Onset Seizures.** Patients with new-onset, alcohol-related seizures should be thoroughly evaluated. This includes alcoholics who claim to have had seizures but for whom no documentation or appropriate evaluation is available. Metabolic disorders, toxic ingestion, infection, and structural abnormalities should be considered.

If the initial physical examination findings, imaging studies, and laboratory test results are within normal limits, patients who remain seizure-free and symptom-free, with no sign of withdrawal after 4 to 6 hours of observation, may be discharged. It may be unclear whether the patient has had a pure alcohol withdrawal seizure or a new-onset seizure disorder in the setting of alcohol ingestion.Long-term treatment with antiepileptic drugs is not useful in unprovoked new-onset seizures that have resolved or when a clear relation to alcohol consumption can be identified.

Optimal outpatient treatment includes follow-up and referral to a detoxification or rehabilitation program. Ideally, the help of a concerned family member or friend who is not a drinking partner and can remain with the patient for at least 1 or 2 days is helpful.

**Prior History of Seizures During Withdrawal.** The risk of seizure increases significantly in alcoholic patients with manifestations of alcohol withdrawal who relate a history of alcohol withdrawal seizure. Detoxification with benzodiazepines reduces alcohol withdrawal seizure and should be initiated early because most seizures occur within the first 24 hours after alcohol withdrawal. An initial dose of 2 mg of lorazepam or 5 mg of diazepam can be given IV. These doses frequently need to be repeated.

**Abnormal Neurologic Examination**

**New-Onset Partial Seizures.** Partial seizures account for up to 50% of alcohol-related seizures. Conversely, studies have
shown that approximately 20% of patients with partial alcohol-related seizure have structural lesions—hematomas, tumors, vascular abnormalities, or stroke. These primary causes of partial alcohol-related seizure, such as prior head trauma, may be easily missed in the history taking. As a result, an emergent CT scan is indicated to evaluate new-onset partial seizures. The patient with a history of a focal alcohol-related seizure who has been previously evaluated does not require an emergency CT scan provided a return to baseline occurs promptly.

Patients Taking Phenytoin Anticonvulsant

Phenytoin has no significant benefit over placebo in the prevention of recurrence of uncomplicated alcohol withdrawal seizure. Considering the risks of phenytoin and no demonstrated benefit in the setting of alcohol withdrawal seizure, it is not indicated for the treatment of alcohol withdrawal seizures. The sudden withdrawal of phenytoin may potentiate the convulsive effects of alcohol withdrawal.

A patient currently taking antiepileptic drugs for an antecedent seizure disorder who presents with a seizure while intoxicated falls into a different category. Such an episode could be an isolated event in a usually compliant patient without a history of chronic alcohol abuse. In this patient, a seizure in the setting of a subtherapeutic antiepileptic drug level may represent the consequences of noncompliance with antiepileptic medication or sleep deprivation versus alcohol withdrawal seizure.

DISPOSITION

Most patients with acute alcohol intoxication are managed in the ED or ED observation unit and then discharged home. Patients who achieve sufficient sobriety to be ready for discharge are offered detoxification or alcohol treatment. Most alcoholics suffer from a combination of medical, psychiatric, and social problems. Hospitalization may be necessary to diagnose and treat these multiple problems. Moreover, with alcoholics who are no longer able to care for themselves, hospitalization is often dictated for this reason alone. Unfortunately, many managed care and Medicaid plans limit or do not cover inpatient detoxification. In choosing medical versus psychiatric admission, a medical illness usually takes priority. Optimal outpatient therapy for chronic alcoholics includes the involvement of concerned family or friends to ensure that the patient takes his or her medications properly, keeps follow-up appointments, abstains from alcohol, and maintains an adequate diet. Alcoholic patients who undergo outpatient treatment need close supervision; therefore, a follow-up clinic appointment within 24 to 48 hours should be considered.

Acute Intoxication

Acute intoxication alone seldom requires admission. However, a combined alcohol-drug overdose or associated medical, psychiatric, or social problems may require hospitalization. Acute alcohol intoxication is a diagnosis of exclusion reached after adequate observation to ensure that the altered mental status resolves. Alcohol levels that may be tolerated by an adult can be lethal in children. It is prudent to admit children with acute intoxication unless close psychosocial follow-up can be ensured. Children presenting with hypoglycemia or medical complications should be admitted. Child abuse or neglect should be considered.

Alcohol Withdrawal

Outpatient treatment consists of lorazepam, 1 to 2 mg tid tapered during 3 to 6 days, chlordiazepoxide, 25 to 100 mg tid tapered during 3 to 6 days, or diazepam, 30 mg once daily tapered during 5 days, depending on the severity of symptoms. Adequate diet, abstinence, and participation in a rehabilitation program in the community are also desirable. Any patient requiring 300 mg of chlordiazepoxide or 60 mg of diazepam/day to control withdrawal should be considered for admission.

Patients with signs of major withdrawal (fever, hallucinations, confusion, extreme agitation) require admission. Patients with mild alcohol withdrawal can be observed in the ED. After 4 to 6 hours of observation and treatment, the alert oriented patient whose vital signs, physical examination findings, and results of appropriate laboratory analysis are within normal limits may be released with appropriate medications and aftercare instructions. Nevertheless, the patient requires treatment for the underlying disease of alcoholism and should be advised or referred accordingly.

Seizures

The alcoholic patient with a first-time, alcohol-related seizure may be discharged to a suitable social situation in these situations: (1) when the patient’s alcohol withdrawal is mild and controlled by supportive care or low-dose benzodiazepines; (2) the diagnostic evaluation, including a head CT scan, is unremarkable; (3) the patient has had fewer than two seizures; and (4) the patient has been observed to be alert and oriented, with normal vital signs, physical examination findings, and laboratory study results during the 6 hours since the last seizure, and appropriate outpatient follow-up can be ensured.

Patients with a documented history of alcohol-related seizures can be discharged if they have had no more than two alcohol-related seizures during a 6-hour period, with a lucid interval between seizures, and are observed to be seizure-free and at baseline mental and physical status for at least 6 hours after their last alcohol-related seizure. Three to five brief, self-limited seizures may occur with alcohol withdrawal seizure. We recommend prolonged observation in the ED or ED observation unit for patients with two or more seizures because of the potential for deterioration to status epilepticus. Such patients should be observed until at least 6 hours has passed since their last seizure and they have a normal neurologic examination, including normal mental status.

Patients with partial seizures or focal neurologic findings on physical examination require admission unless these findings have been previously documented. Patients with seizures associated with head trauma or mixed alcohol-drug withdrawal are admitted. Status epilepticus or recurrent seizures during ED observation indicate a lack of seizure control and also require hospitalization.

Psychiatric and Social Problems

Alcoholic patients requiring admission with acute intoxication, alcohol-related seizure, alcohol withdrawal, or medical or surgical disorders are usually best managed in acute care units rather than by a general psychiatric service. Some psychiatric and social conditions in the alcoholic can be better handled on a general psychiatric unit—psychosis, exacerbation of schizophrenia, depression with suicidal tendencies, any patient who is a danger to self or others, or alcoholic hallucinosis with an otherwise clear sensorium.

Patients who are no longer able to care for themselves may also require admission. Although these patients’ ultimate destination is a rehabilitation center or a board and care program, hospitalization may be necessary to rule out medical or psychiatric illness and treat impending withdrawal symptoms. Patients who wish to stop drinking are usually referred to a detoxification unit for treatment of impending withdrawal. Data and interest are increasing for outpatient drug therapy for alcohol dependence. The FDA has
approved disulfiram, naltrexone, acamprosate, and topiramate for the treatment of alcohol dependence. There is growing evidence that patients with alcohol dependence who carry a particular variant of an opioid receptor gene are more likely to respond to naltrexone, raising the possibility that genetic tests may one day guide medication selection. Naltrexone, ondansetron, acamprosate, and acamprosate plus naltrexone have had mixed results facilitating abstinence. The role of medications in combination with behavioral therapy is being actively investigated.

Several other medications are under active study and are sometimes prescribed for alcoholism treatment on an unapproved or off-label basis. Baclofen, because of its anticraving action and safety, could have an important role for the treatment of alcohol-dependent patients with advanced liver disease. Gabapentin is used as monotherapy or as add-on pharmacotherapy in outpatient settings in the control of alcohol consumption and craving and in helping patients achieve abstinence. Ondansetron may show benefit in early-onset but not in late-onset alcoholics.

Brief intervention and screening (SBIRT—screening, brief intervention, and referral to treatment) is valuable and is now recommended in the ED. Internet-based interventions show promise for reducing alcohol consumption, especially among those meeting criteria for hazardous or harmful drinking. Telephone contact after the ED visit may be another effective tool to screen injured patients for hazardous drinking and offer a brief intervention while avoiding interruptions to patient flow. Most communities have an Alcoholics Anonymous (AA) chapter or treatment center for anyone who desires help with alcohol. In smaller communities, clergy or social workers can usually arrange rehabilitation.

**KEY CONCEPTS**

- Moderate alcohol consumption is defined as one or two drinks/day for men and one drink/day for women.
- Benzodiazepines are the main treatment of alcohol withdrawal and alcohol withdrawal seizures. Minor alcohol withdrawal occurs as early as 6 hours and usually peaks at 24 to 36 hours after the cessation of or significant decrease in alcohol intake.
- Major alcohol withdrawal occurs after 24 hours and usually peaks at 50 hours (but occasionally takes up to 5 days) after the decrease or termination of drinking.
- Delirium tremens is the extreme end of the alcohol withdrawal spectrum; it consists of gross tremors, profound confusion, fever, incontinence, and frightening visual hallucinations.
- Alcohol withdrawal seizures occur 6 to 48 hours after the cessation of drinking, with 60% of patients experiencing multiple seizures within a 6-hour period.
- Alcohol withdrawal should be assessed and managed using a validated scale, such as the CIWA-Ar scale.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
142.1. A 56-year-old man presents with altered mental status. You recognize the patient as a frequent visitor to the emergency department (ED) for alcohol intoxication. He is drowsy but arousable to painful stimuli. He is confused. Vital signs are within normal limits, and there is no evidence of trauma. His blood glucose level is 30 mg/dL. Which treatment is indicated first?

A. Dextrose  
B. Folate  
C. Glucagon  
D. Naloxone  
E. Thiamine

**Answer:** A. Although alcohol intoxication clearly causes altered mental status (AMS), it should never be assumed that AMS is due to alcohol intoxication. Alcoholics are at risk for multiple medical and traumatic causes of AMS. Chronic alcoholics have decreased glycogen stores and frequently experience hypoglycemia. Because glucagon works by mobilizing glycogen stores, it is often not effective in alcoholics. Thiamine and folate stores are often depleted in chronic alcoholics, alcohol consumption is not required. Treatment is indicated if low. Magnesium levels should be checked and treated if low. Magnesium is a cofactor for thiamine and is often depleted in chronic alcoholics.

142.2. A 62-year-old man presents with agitation, confusion, and fever. He is noted to experience visual hallucinations during your interview. His vital signs reveal hypertension, tachycardia, and fever. Physical examination is otherwise unremarkable. Diagnostic studies (including head CT and lumbar puncture) are nonspecific. Which diagnosis is most consistent with this patient’s presentation?

A. Acute schizophrenia  
B. Alcohol withdrawal  
C. Anticholinergic poisoning  
D. Opioid withdrawal  
E. Thyrotoxicosis

**Answer:** C. Criteria to diagnose Wernicke’s encephalopathy require two of the following: (1) dietary deficiencies; (2) oculomotor abnormalities; (3) cerebellar dysfunction; and (4) AMS or mild memory impairment. Although it is most often diagnosed in alcoholics, alcohol consumption is not required. Treatment is with replacement of dietary deficiencies, particularly thiamine. Magnesium levels should be checked and treated if low. Magnesium is a cofactor for thiamine and is often depleted in chronic alcoholics.

142.3. In addition to altered mental status (AMS), which of the following is a criterion for diagnosing Wernicke’s encephalopathy?

A. Alcohol intoxication  
B. Fever  
C. Oculomotor abnormalities  
D. Recent glucose administration  
E. Seizure

**Answer:** E. Patients are often confused and agitated and exhibit autonomic instability, resulting in hypertension, tachycardia and, often, fever. Hallucinations are typically visual. Schizophrenia typically results in auditory hallucinations and, although patients are delusional, they are not typically confused. Patients with anticholinergic poisoning typically present with confusion but also have dry mouth, dry eyes, dry skin, hypoaemic bowel sounds, and urinary retention. Patients with opioid withdrawal typically have gastrointestinal complaints and, although they may be agitated, they are seldom confused or febrile. Thyrotoxicosis is much more common in women, and patients can exhibit lid lag, tremor, and gastrointestinal complaints.
CHAPTER 143
Acetaminophen
Robert G. Hendrickson  Nathanael J. McKeown

PRINCIPLES OF TOXICITY
Acetaminophen (better known internationally as paracetamol) is one of the most important toxins encountered in emergency care because of its ready availability, high lethality, and absence of clinical indications of ingestion until the time to administer the effective antidote has passed. Acetaminophen is found as an isolated product or in combination medications for the treatment of pain and febrile illness. An intravenous (IV) formulation is also available in the United States and Europe.1,2 Given its widespread availability and occult clinical presentation, acetaminophen toxicity is a concern in the vast majority of intentional ingestions, as well as with repeated supratherapeutic dosing, prescription drug abuse, and use by alcoholic patients. Acetaminophen toxicity is one of the leading causes of hospital admission, antidote use, and fatalities from oral poisonings in the United States.3

Protocols have been established for the assessment and management of acute and chronic acetaminophen ingestion through decades of research and experience; however, controversy continues to exist, and with new formulations recently approved, the management of acetaminophen exposures continues to evolve.

Acetaminophen is absorbed rapidly, with peak plasma concentrations generally occurring within 1 hour and complete absorption within 4 hours. Once absorbed, acetaminophen inhibits prostaglandin E2 (PGE2) synthesis, leading to antipryrexia and analgesia. Inhibition of PGE2 synthesis is either by direct cyclooxygenase-2 (COX-2) inhibition or inhibition of membrane-associated prostaglandin synthase.

In therapeutic doses, acetaminophen is primarily metabolized by conjugation with glucuronide (40% to 67%) and sulfate (20% to 46%) into nontoxic metabolites that are excreted in the urine (Fig. 143.1).4 A small percentage (<5%) is oxidized by cytochrome P450 2E1 (CYP2E1) (and to a lesser extent 1A4 and 3A4) to a highly cytotoxic metabolic intermediary, N-acetyl-p-benzoquinone imine (NAPQI).5 In therapeutic doses, NAPQI is short-lived, combining rapidly with glutathione and other thiol-containing compounds to form nontoxic metabolites that are excreted in the urine. With typical therapeutic acetaminophen dosing, glutathione stores and the ability to regenerate glutathione easily detoxify any NAPQI that is produced.

Even after acetaminophen hepatotoxicity is evident, NAC acts as a free-radical scavenger and an antioxidant and alters hepatic microcirculation and oxygen delivery. In patients with acetaminophen-induced hepatic failure, IV NAC decreases the rates of cerebral edema, hypotension, and death even when no detectable acetaminophen remains in the serum.6

CLINICAL FEATURES
Early after acute acetaminophen ingestion, patients may be asymptomatic or have mild nonspecific symptoms (eg, nausea, vomiting, anorexia, malaise, and diaphoresis) (Table 143.1). Liver injury becomes evident after a period of 8 to 36 hours as an elevation in aspartate transaminase (AST).7 Once liver injury has begun, patients may develop right upper quadrant (RUQ) pain or tenderness, vomiting, and jaundice. AST concentrations continue to rise rapidly and usually peak in 2 to 4 days, corresponding to maximal liver injury.8 Alanine transerase (ALT), prothrombin time (PT), and bilirubin typically begin to rise and peak several hours after AST values. With severe toxicity, ALT and the PT may all be elevated within 24 hours (Fig. 143.2).9 With maximal liver injury, patients develop signs and symptoms consistent with fulminant liver failure, including metabolic acidosis, coagulopathy, and hepatic encephalopathy. Death may occur from hemorrhage, adult respiratory distress syndrome, sepsis, multiorgan failure, or cerebral edema. The risk of renal injury increases with the severity of hepatic injury (hepato renal syndrome), occurring in less than 2% of patients without hepatotoxicity and in 25% of patients with severe hepatotoxicity.

If patients recover, aminotransferases return to baseline concentrations over a 5- to 7-day period (see Fig. 143.2), although complete histologic resolution of liver injury may take months. Once histologic recovery is complete, there are no long-term sequelae to the liver and patients are not at risk for chronic hepatic dysfunction.

DIFFERENTIAL DIAGNOSES
Acetaminophen poisoning should be on the differential diagnosis in patients with intentional oral overdoses regardless of whether they state that they ingested acetaminophen. In patients with elevations in aminotransferases, bilirubin, partial thromboplastin time (PTT)/international normalized ratio (INR), or creatinine, other
sources of injury should be considered, including acute tubular necrosis, rhabdomyolysis, ischemic hepatitis, alcoholic hepatic disease, cyclopeptide-containing mushroom toxicity, viral hepatitis, Wilson disease, and other hepatic toxicities (eg, valproic acid, isoniazid [INH], statins, herbal medications, vinyl chloride, and polychlorinated biphenyls).

**DIAGNOSTIC TESTING**

The goals of patient assessment after acetaminophen ingestion are (1) the determination of the patient’s risk, (2) diagnostic testing, and (3) treatment with the antidote NAC when appropriate.

Acetaminophen exposures may be classified as acute or chronic, and each type requires different testing and risk assessment. An acute ingestion is generally considered to be a single ingestion or a series of ingestions that are arbitrarily defined to occur within an 8-hour period. All other ingestions, including accidental repeated supratherapeutic ingestions and intentional ingestions spread over longer than 8 hours, can be considered to be chronic.

**Risk Assessment With Acute Acetaminophen Ingestion**

The initial diagnostic strategy of an acute ingestion is well established. The first step is to determine the patient’s risk of acute acetaminophen exposure. Patients who report an acute intentional ingestion of acetaminophen should have laboratory risk stratification regardless of the reported amount ingested. In an adult patient, significantly greater than 10 grams in total or 150 mg/kg (approximately forty 325 mg [regular strength] or twenty-five 500 mg [extra strength] tablets for an 80 kg adult) in an acute ingestion is generally required before significant liver toxicity occurs; however, history alone may not be reliable. We recommend a serum acetaminophen concentration in any intentional overdose patient who admits to taking acetaminophen (regardless of the admitted dose) or had access to acetaminophen, even if they deny taking it. Acetaminophen is detected in the serum of up to 8% of patients with intentional ingestions who deny acetaminophen ingestion. Also there is a high prevalence (18%) of unrecognized acetaminophen toxicity among subjects presenting with indeterminate acute liver failure.7

When acute acetaminophen overdose is identified, the time of ingestion is established as accurately as possible using all available information. If no accurate time of ingestion can be determined, it is best to base further evaluation and therapy on a scenario that assumes the earliest possible time of ingestion.

A serum acetaminophen concentration 4 hours post-ingestion, or as soon as possible after 4 hours is needed to determine the need for antidotal therapy by plotting the serum acetaminophen concentration against the time since ingestion on the treatment

![Fig. 143.1. Acetaminophen (APAP) metabolism and N-acetylcysteine (NAC) mechanisms of action. nomogram (Fig. 143.3), an adaptation of the Rumack-Matthew nomogram. If the serum acetaminophen concentration is on or above the treatment line (that starts at 150 μg/mL at 4 hours and decreases to 4.7 μg/mL at 24 hours), this indicates the need for treatment with NAC. If the serum acetaminophen concentration is below the treatment line and the most severe possible scenario has been taken for the time of ingestion, then the patient requires no antidote. Use of the treatment line is a highly sensitive approach and may be used for patients presenting after acute ingestions. Alternative approaches in patients with alcoholism, patients with co-ingestions of antimuscarinic agents, patients with unknown ingestion times, and after IV formulations have been suggested, but these remain unsubstantiated.10 We recommend adherence to the approach that is described earlier.

Measurement of serum acetaminophen concentration prior to 4 hours is not necessary. Although a serum acetaminophen concentration less than 10 μg/mL between 1 and 4 hours after ingestion likely excludes significant ingestion of acetaminophen, there are insufficient data on which to base this conclusion. Absorption of acetaminophen may not be complete prior to 4 hours, and any serum acetaminophen concentration greater than 10 μg/mL is difficult to interpret. Finally, serum acetaminophen concentrations measured prior to 4 hours cannot be plotted on the treatment nomogram. Fortunately, there is little need to treat patients prior to 8 hours after ingestion, because patients treated with NAC up to 8 hours after ingestion, even after very large doses, have no increased risk of hepatotoxicity regardless of their serum acetaminophen concentration.11 For patients with potential hepatotoxicity due to the total amount ingested, or those with preexisting liver disease in whom a serum acetaminophen concentration cannot be obtained prior to 8 hours after ingestion, a loading dose of NAC should be given, or consultation obtained with a medical toxicologist or poison center.

Iatrogenic acetaminophen toxicity related to IV dosing is exceedingly rare. Pharmacokinetics are different after a large IV acetaminophen overdose, and the nomogram is based entirely on oral ingestion. When the extremely rare occurrence of acetaminophen toxicity related to IV administration is encountered, we recommend treatment with NAC if the patient received greater than 60 mg/kg IV acetaminophen in one dose or has a serum acetaminophen concentration greater than 50 μg/mL at 4 hours after the infusion stops.10 Consultation with a regional poison center or medical toxicologist is advisable if there is uncertainty about whether to administer NAC.

**Risk Assessment With Chronic Ingestion**

With repeated or chronic exposure, risk assessment is more complex, and the treatment nomogram cannot be used. Determination of the need for NAC is based on assessment of the risk for hepatotoxicity and measurement of serum levels of acetaminophen and AST.

The risk of hepatotoxicity from chronic ingestion of acetaminophen increases with total dose of acetaminophen and the duration over which it has been ingested in supratherapeutic quantities. Laboratory testing for serum acetaminophen concentration and AST should be initiated in any patient who fits the criteria in Table 143.2.10

Ingestion of therapeutic amounts of acetaminophen appears to be quite safe. However, rare reports of aminotransferase elevation and liver injury during therapeutic dosing suggest that some patients may be at increased risk for liver injury, possibly due to genetic variation or to specific risk factors. Patients who chronically ingest INH or ethanol may have increased CYP2E1 activity and, theoretically, may be at higher risk for chronic acetaminophen toxicity. Similarly, patients who are malnourished or have severe dehydration may be at higher risk for hepatotoxicity.

Once serum acetaminophen concentration and AST are obtained, further risk assessment is necessary. Conceptually, patients with chronic ingestions (ie, >4 grams/day over a period of several days) may benefit from antidotal therapy if they have evidence of liver injury (AST >2× normal, or 120 IU/L) or if they have evidence of acetaminophen excess (serum acetaminophen >30 mcg/mL) with a prolonged half-life that may lead to liver injury.12 (Of note, after a typical therapeutic dose of acetaminophen, serum acetaminophen concentration peaks below 30 μg/mL and is less than 10 μg/mL at 4 hours.)

**Risk Assessment in Pregnant Women**

The risk assessment and diagnostic approach to pregnant women is the same as for nonpregnant women. In acute overdoses, a
serum acetaminophen concentration should be drawn and plotted on the treatment nomogram. NAC therapy should be initiated if the serum acetaminophen concentration plots above the treatment line. With chronic exposure, the same criteria strategy as outlined earlier should be instituted.

**MANAGEMENT**

**Stabilization and Supportive Care**

In addition to supportive care as needed, the mainstay of management is the initiation NAC therapy when indicated. Where doubt exists regarding initiation of NAC or there are confounding clinical issues present (eg, preexisting liver disease), clinicians may consult with a regional poison center (1-800-222-1222) or medical toxicologist for advice. Supportive care includes management of co-ingestions, and the nausea and vomiting, hepatic injury, and renal dysfunction related to acetaminophen poisoning. Treatment of these problems is based on general treatment principles and is not acetaminophen-dependent (see Chapters 80 and 87).

**Decontamination**

Activated charcoal (AC) effectively binds acetaminophen in vitro, and some limited studies have suggested that early administration of AC (within 1 to 2 hours post-ingestion) may decrease the number of patients that require antidotal therapy. However, many patients have co-ingestions that may decrease mental status, and patients with severe acetaminophen poisoning often develop vomiting, thus increasing the risk for aspiration of AC. Therefore, use of AC should have no bearing on the determination of the need for NAC therapy. Given the lack of demonstrated efficacy in terms of improved outcome, and the risk of adverse outcome from aspiration of AC, we do not recommend the use of AC for acetaminophen overdose when NAC therapy is readily available within 8 hours following an acute potentially hepatotoxic ingestion.

**Enhanced Elimination**

Hemodialysis is not routinely used for acetaminophen overdose, because there is a highly effective antidote with good clinical outcomes when given within 8 hours of ingestion. However, hemodialysis may be helpful when the absorbed acetaminophen burden is sufficient to cause hepatotoxicity despite usual doses of NAC. We recommend consultation with a poison center or medical toxicologist for initiation of hemodialysis for patients presenting following an acute massive ingestion with the characteristics shown in Box 143.1. There is no definitive evidence regarding the efficacy of hemodialysis in this setting, but removal of excess acetaminophen may prevent hepatotoxicity by allowing the NAC to effectively deal with the reduced burden of toxin.14,15

**PO**/Intravenous; **NAC**, N-acetylcysteine; PO, per os (by mouth).

**BOX 143.1**

**Indications for Emergent Hemodialysis Following Acute Acetaminophen Ingestion**

- **Highly elevated serum acetaminophen concentration (>1000 mg/L) at 4 hours post-ingestion**
- Hepatorenal syndrome (Cr >3.5)
- Metabolic acidosis with pH <7.30
- Encephalopathy
- Elevated lactate (>3.5 mmol/L)

**Antidote Therapy**

**N-Acetylcysteine**

When indicated, NAC should be administered as early as possible. Delay of NAC more than 8 hours after ingestion increases the risk of hepatotoxicity (Fig. 143.4).

NAC can be administered **per os (by mouth; PO)** or IV. Both methods are efficacious in most situations, with advantages and disadvantages for each. All formulations of NAC (PO or IV) are very effective when started within 8 hours of ingestion.16,17 When administered early (<8 hours), NAC’s main role is to prevent hepatotoxicity by detoxifying NAPQI and decreasing NAPQI production. The risk of liver injury (ie, AST >1000 IU/L) in patients treated with NAC within 8 hours is less than 4% and the mortality rate approaches zero (see Fig. 143.4).16

Both PO and IV NAC are equally effective in treating patients who present 8 to 24 hours after ingestion, although those patients with vomiting or hepatic encephalopathy may be unable to tolerate the oral formulation.

Once liver failure (eg, coagulopathy, encephalopathy, and so on) is evident, however, NAC is given intravenously.9 IV NAC decreases the risk of hypotension, cerebral edema, and death in patients with acetaminophen-related hepatic failure.9 Oral NAC should only be used if IV NAC is not available.

The main differences between IV and PO NAC are in their side effect profiles (Table 143.3). Approximately 2% to 6% of patients treated with IV NAC develop significant anaphylactoid reactions, although rates of up to 30% have been reported in prospective trials. The majority of these symptoms are mild and consist of transient skin rashes and
flushing. More severe reactions have been reported in less than 1% of patients and include angioedema, bronchospasm, hypotension, and rarely death. Symptoms typically occur within 30 minutes of the start of the loading infusion. These anaphylactoid reactions are dose, rate, and concentration-dependent.

Anaphylactoid reactions are much less frequent with PO NAC. Skin rash, serious systemic reactions, and anaphylactic reactions are rarely reported with the PO formulation. However, approximately 13% of patients receiving PO NAC vomit (versus 7% with IV NAC), delaying timely antidote delivery. PO NAC is extremely unpalatable largely due to a sulfur or “rotten egg” odor and taste. Palatability may be improved by administering NAC diluted with either soda or juice and serving it in a covered container through a straw. Any dose that is vomited within 1 hour of administration should be repeated. If vomiting occurs, we recommend ondansetron in a 4 mg dose for adults. However, we do not recommend routine “prophylactic” use of antiemetics.

Anaphylactoid reactions to IV NAC are typically mild (eg, flushing) and occur during the initial 15- to 60-minute infusion. Mild reactions can be managed with parenteral diphenhydramine, 25 mg IV, without stopping the infusion. For more serious reactions, with hypotension, we recommend slowing or pausing the infusion, giving a 500 mL fluid crystalloid bolus, and administering diphenhydramine, 25 mg IV. For reactions persisting despite these steps, administer methylprednisolone 120 mg IV and take other actions as indicated for severe allergic reaction. Epinephrine is rarely required. Although these reactions require close observation and treatment, they do not preclude subsequent doses, but pretreatment with diphenhydramine is advised.

Use in Pregnancy

Acetaminophen crosses the placenta, but the fetus in the first trimester of development is only at risk for injury if the mother suffers hepatoxicity because fetal CYP enzymes have not fully developed. However, if the fetus is near-term (third trimester of development), there is a risk for direct fetal/neonatal hepatotoxicity, because the liver system is more developed at this stage. Treating the mother with NAC is safe and effective, and NAC effectively crosses the placenta. NAC is used with the same protocols as for the nonpregnant patient. Administration of IV NAC to the mother has the theoretical advantage of increased NAC delivery to the fetus compared to PO NAC. IV administration circumvents first-pass metabolism, presumably exposing the fetal circulation to higher maternal serum concentrations. Based on large published studies, we recommend 21 hours of therapy with the IV protocol following an acute ingestion, or alternatively, 72 hours with the oral protocol if the IV preparation is unavailable, as described later.

Duration of Therapy. There are two well-established protocols for NAC administration in cases of acute acetaminophen toxicity: a 21-hour IV protocol and a 72-hour PO protocol. The standard IV NAC protocol in adults is a loading dose of 150 mg/kg up to a maximum of 15 gm in 200 mL of dextrose 5% in water (D5W) infused over 60 minutes followed by a first maintenance dose of 50 mg/kg (up to a maximum of 5 gm) in 500 mL D5W infused over 4 hours followed by a second maintenance dose of 100 mg/kg (up to a maximum of 10 gm) in 1000 mL D5W infused over 16 hours (6.25 mg/kg/hour).

When NAC is administered orally, the patient should receive a 140 mg/kg loading dose, either orally or by enteral tube. Starting 4 hours after the loading dose, 70 mg/kg should be given every 4 hours for an additional 17 doses (total treatment duration of 72 hours).

Several other regimens, including 48 hours IV, 36 hours IV, 36 hours PO, and 20 hours PO protocols are described; however, none of these has been adequately studied for general use. For delayed, chronic, or supratherapeutic toxicity, NAC therapy should continue until acetaminophen is undetectable in the serum (<10 mcg/mL) and any signs of liver injury have resolved (ie, encephalopathy has cleared, normalization of the coagulation profile, resolution of metabolic acidosis) and the AST is less than 1000 IU/L with demonstration of a downward trend.

CHAPTER 143: QUESTIONS & ANSWERS

143.1. Which of the following is true regarding pregnant patients with an acute acetaminophen ingestion?
A. All pregnant women should be treated with N-acetylcysteine (NAC) after any known ingestion of acetaminophen
B. Pregnant women in the third trimester should be treated with NAC if their acetaminophen concentration is ever elevated above 50 µg/mL
C. Pregnant women should be treated with NAC if their acetaminophen concentration is above the Treatment Line on the nomogram
D. Pregnant women should be treated with NAC if they ingest >75 mg/kg PO acetaminophen over less than 8 hours
E. The Treatment Line on the nomogram is lowered to a line starting at 100 µg/mL at 4 hours after ingestion

Answer: C. Pregnant patients with an acute ingestion of acetaminophen should have the same initial treatment as nonpregnant patients. After measurement of an acetaminophen concentration, plotting of the acetaminophen concentration on the nomogram treatment with NAC should be given if the concentration is above the Treatment Line on the nomogram.

Both acetaminophen and NAC do cross the placenta, but the fetus is at risk only if the mother becomes ill. Patients with first trimester pregnancies are at risk of miscarriage if the mother becomes ill, and fetuses that are near-term may be at risk for fetal/neonatal hepatotoxicity.

143.2. A 3-year-old boy with intractable vomiting and fever is treated with intravenous (IV) acetaminophen. He is given a tenfold dosing error (150 mg/kg instead of 15 mg/kg). Which of the following is one of the current criteria for treatment of his overdose?
A. Treat with N-acetylcysteine (NAC) if the 4-hour acetaminophen concentration is above 50 µg/mL
B. Treat with NAC for any IV dose greater than 15 mg/kg

Answer: C. Treat with NAC for any IV dose greater than 4 grams
D. Treat with NAC only if the 2-hour acetaminophen concentration is above the Treatment Line
E. Treat with NAC only if the 4-hour acetaminophen concentration is above the Treatment Line

Answer: A. Although data is limited, the current recommendations for treatment with NAC of an IV acetaminophen overdose is (1) treat for any dose >60 mg/kg or (2) treat if the 4-hour acetaminophen concentration is >50 µg/mL.

143.3. A 30-year-old woman presents with drowsiness, nausea, and vomiting. She reports taking several pills in a suicide attempt. Despite your best efforts, she cannot describe what she ingested or how many she ingested. She states she took the pills “last night” and refuses to be more specific. Currently, it is 6 AM. A family member is present and found the patient vomiting at 4 AM, at which time she informed the family member she took some pills. The family member further states that the patient was in an argument with a friend at 12 PM and may or may not have ingested the pills at that time. The family was with the patient at 8 PM and is sure that she had not ingested the pills at that time. What time should be used as the time of ingestion?
A. 2 AM—the time that is 4 hours prior to presentation
B. 4 AM—the time the patient was found abnormal
C. 6 AM—the time of presentation
D. 8 PM—the time the patient was last seen and known to be prior to the ingestion
E. 12 PM—the time the patient was last seen prior to becoming symptomatic

Answer: D. If the exact time of ingestion cannot be determined, then the “worst case” scenario should be assumed. The longer a patient goes without therapy, the worse the outcome. Therefore, the time of ingestion should be assumed to be the last time the patient was seen normal prior to any possible ingestion.
143.4. A 20-year-old man is brought to the emergency department by family with a complaint of “overdose.” The patient is drowsy but arousable. His vital signs are normal. His physical examination is normal except for appearing to be intoxicated. He has no complaints. The family reports the ingestion of unknown “pills” as well as alcohol and possibly “street drugs.” The ingestion occurred approximately 6 hours ago after an argument. Routine supportive care is initiated. What test must be ordered on this patient because it may affect the immediate treatment plan?
A. Acetaminophen concentration  
B. Chest radiograph  
C. Head computed tomography (CT) scan  
D. Serum alcohol concentration  
E. Urine drug screen  

Answer: A. The antidote is given as soon as possible after ingestion, but definitely within 8 hours to prevent toxicity.

143.5. What is the typical peak serum acetaminophen concentration after a therapeutic oral ingestion?
A. Undetectable  
B. 10 µg/mL  
C. 30 µg/mL  
D. 50 µg/mL  
E. 100 µg/mL  

Answer: C. This concentration is typically reached approximately 1 hour after ingestion. Four hours after a therapeutic ingestion, the concentration is typically less than 10 µg/mL. Concentrations higher than this should lead one to consider the possibility of chronic ingestion or a person who does not properly metabolize acetaminophen.

143.6. Two 20-year-old patients present to the emergency department 1 hour after ingesting 15 grams of acetaminophen each in a suicide pact. You are confident of the time of ingestion and that time is confirmed by text messages sent by the patients. Patient A has a 4-hour acetaminophen concentration of 130 mg/dL. Patient B’s 4-hour acetaminophen concentration is 170 mg/dL. What is the appropriate treatment for both patients?
A. Neither patient requires treatment because the acetaminophen concentrations are below the treatment cutoff.  
B. Neither patient requires treatment because they received activated charcoal (AC).  
C. Patient A should receive immediate N-acetylcysteine (NAC); patient B should not receive NAC.  
D. Patient A should not receive NAC; patient B should receive immediate NAC treatment.  
E. Both patients should receive immediate NAC treatment.  

Answer: D. In this case, your confidence of the time of ingestion is high. The Treatment Line crosses 150 mg/dL at 4 hours. Therefore, if the 4-hour acetaminophen concentration is >150 mg/dL, treatment is indicated. In the case above, patient A does not require NAC therapy, but patient B does require treatment with NAC.

143.7. What is the antidote for acetaminophen ingestion?
A. Dicemcaprol  
B. Hydroxycobalamin  
C. N-acetylcysteine (NAC)  
D. N-acetyl-p-benzoquinone imine (NAPQI)  
E. Succimer  

Answer: C. Hydroxycobalamin is an antidote for cyanide; succimer is an antidote for lead; and dimercaprol is an antidote for arsenic, lead, and mercury. NAPQI is the toxic metabolite of acetaminophen.

143.8. A 42-year-old man presents to the emergency department with complaints of nausea and vomiting. He has no other complaints. His symptoms started approximately 12 hours ago. His history is significant for “back pain,” which has been worse than normal recently. He states that he finished a bottle of 60 “pain pills” during the past 2 days. His vital signs are normal. Other than right upper abdominal tenderness, his physical examination is normal. Routine laboratory tests including complete blood count, chemistry, and liver panel are normal except an aspartate transaminase (AST) concentration of 265 IU/L. You are concerned for possible repeated supratherapeutic acetaminophen poisoning. What should you do next?
A. Admit the patient for observation and repeat AST testing; because this is a repeated supratherapeutic ingestion, treatment with N-acetylcysteine (NAC) is not beneficial.  
B. Initiate treatment with activated charcoal (AC) now.  
C. Initiate treatment with NAC now.  
D. Obtain two serum acetaminophen concentrations 1 hour apart to determine the drug’s elimination half-life to decide if treatment with NAC is indicated.  
E. Plot the acetaminophen concentration on the acetaminophen treatment nomogram to determine if treatment with NAC is indicated.  

Answer: C. Many prescription and nonprescription analgesics contain acetaminophen, so although a patient may deny use of acetaminophen, suspicion should remain high. A patient with chronic acetaminophen ingestion should have an AST and acetaminophen concentration checked. If either is abnormal, treatment with NAC should be initiated. Many patients with repeated supratherapeutic ingestion will not have a markedly increased acetaminophen concentration, and the treatment nomogram is not used with repeated supratherapeutic dosing. Regardless of how long ago the ingestion occurred, if a patient displays signs or symptoms of liver damage, NAC should be given because it will still have beneficial effects.

143.9. A 55-year-old man is taking 10 grams of acetaminophen per day over the last 8 days for a toothache. He arrives to the emergency department with severe right upper quadrant (RUQ) pain, jaundice, and hypoglycemia. His aminotransferases, bilirubin, and acetaminophen concentration are highly elevated, and he is resuscitated and started on intravenous (IV) N-acetylcysteine (NAC). Which of the following laboratory findings is a very poor prognostic indicator and indicates that he is a candidate for immediate liver transplant?
A. Aspartate transaminase (AST) >10,000 IU/L  
B. Bilirubin >5 mg/dL  
C. Lactate >5 mmol/L  
D. Acetaminophen concentration >150 mg/dL  
E. pH <7.4  

Answer: C. The patient has severe liver failure due to repeated supratherapeutic dosing of acetaminophen. Prognostic variables that are used to determine immediate hepatic transplant are the Kings College Criteria (a pH <7.3 [or lactate >3.5 mmol/L] after resuscitation or the combination of Cr >3.3 and PTT >100s [or INR >5] and grade 3 or 4 encephalopathy). Other criteria that
indicate high mortality are the APACHE II score >20. If a patient in the emergency department meets these criteria, immediate consultation with a hepatic transplant surgeon is indicated.

143.10. A 27-year-old woman is brought to the emergency department by emergency medical service (EMS). The patient is lethargic and cannot provide a history. A suicide note indicates that she ingested 50 g of acetaminophen approximately 24 hours ago. The patient is noted to be jaundiced with right upper quadrant (RUQ) tenderness. General supportive care is initiated. Her aspartate transaminase (AST) is 1072 IU. A serum acetaminophen concentration is pending. Which of the following statements is true regarding treatment with N-acetylcysteine (NAC)?
A. Treatment with NAC should be delayed until the acetaminophen concentration is obtained.
B. Treatment with NAC should be initiated because an ingestion of 50 g of acetaminophen is potentially fatal.
C. Treatment with NAC should be initiated because the patient has liver injury secondary to acetaminophen poisoning.
D. Treatment with NAC will not alter the outcome; this patient will require a liver transplant.
E. Treatment with NAC will not be beneficial as the ingestion occurred more than 10 hours ago.

**Answer:** C. Ideally, NAC treatment is initiated within 8 hours of ingestion, but treatment with NAC is still beneficial even after hepatotoxicity has developed. An acetaminophen concentration should be obtained, but there is no reason to delay treatment. Ingestion of 50 g is potentially toxic, but decisions should be based on the patient’s current condition. Occasionally, hepatotoxicity from acetaminophen is severe and liver transplant is required, but most cases of hepatotoxicity resolve with NAC treatment.
CHAPTER 144

Aspirin and Nonsteroidal Agents

Benjamin W. Hatten

ASPIRIN

Principles of Toxicity

Overview

Aspirin, or acetylsalicylic acid, is widely consumed for its analgesic, antiinflammatory, and antiplatelet effects. Although its therapeutic use is ubiquitous, salicylate toxicity is not a benign condition and causes a complex set of life-threatening metabolic derangements with significant morbidity and mortality.

Epidemiology

In 2013, 26 deaths were reported to United States Poison Control Centers due to aspirin alone. This is consistent with reports to Poison Control Centers of 20 to 30 deaths per year for the last decade. Of note, elderly patients with chronic medical problems and young patients diagnosed with an acute illness are particularly at risk for delay in diagnosis with consequent severe clinical effects.

Salicylate Containing Products

Aspirin is the most common salicylate-containing product. Other potential sources of salicylate toxicity include topical salicylates, oil of wintergreen, willow bark, and bismuth subsalicylate. Ingestion of oil of wintergreen is of particular concern given that 1 mL of 98% solution contains the equivalent salicylate of 1.4 grams of aspirin.

Pathophysiology

Salts of salicylic acid are rapidly absorbed intact from the gastrointestinal (GI) tract, with appreciable serum concentrations occurring within 30 minutes of ingestion of a therapeutic dose and peak levels in 2 to 4 hours. Large ingestions frequently delay gastric emptying. In addition, aspirin, particularly enteric-coated preparations, tend to form concretions in the stomach. These properties often result in prolonged absorption with rising serum levels for 12 hours or more.

In the intestinal wall, liver, and red blood cells, aspirin is hydrolyzed to free salicylic acid, which reversibly binds to albumin. Free salicylate is eliminated by renal excretion. At therapeutic salicylate concentrations, elimination follows first-order kinetics. Once serum salicylate concentrations are greater than 30 mg/dL, elimination follows zero-order kinetics. The metabolic pathways become saturated, and the pH-sensitive urinary excretion of salicylic acid determines the half-life, prolonging significantly (up to 15 to 30 hours) with large overdoses.

The initial physiologic effect of salicylates is direct stimulation of the medullary respiratory center. In addition, they increase the sensitivity of the respiratory center to pH and partial pressure of carbon dioxide (Pco2). Hyperventilation develops early, subsequently becoming a compensatory mechanism for metabolic acidosis. Prolonged high serum concentrations eventually depress the respiratory center. Respiratory alkalosis is compensated by the buffering capacity of the hemoglobin-oxyhemoglobin system, the exchange of intracellular hydrogen ions for extracellular cations, and the urinary excretion of bicarbonate. Loss of bicarbonate decreases buffering capacity and intensifies the metabolic acidosis (Box 144.1).

Toxicity results primarily from salicylate interference with aerobic metabolism by uncoupling of mitochondrial oxidative phosphorylation. Inhibition of the Krebs cycle increases production of pyruvic acid and increases conversion to lactic acid. Increased lipid metabolism generates ketone bodies. Metabolic rate, temperature, tissue carbon dioxide, and oxygen consumption are increased. Tissue glycolysis predisposes to hypoglycemia. Inefficiency of anaerobic metabolism results in decreased production of adenosine triphosphate, with energy released as heat causing the hyperthermia frequently seen in salicylate poisoning.

Only non-ionized particles can cross the lipophilic cell membrane and accumulate in the brain and other tissues. Because salicylic acid has a pH of 3.5, the majority of salicylate is ionized and unable to enter tissue at the physiologic pH of 7.4. However, as serum pH decreases, more particles become un-ionized and cross the cell membrane and blood-brain barrier, markedly increasing the movement of salicylate into the tissues and central nervous system (CNS).

The rapid depletion of potassium stores in salicylate toxicity is caused by multiple factors. These include vomiting, which is secondary to stimulation of the medullary chemoreceptor trigger zone; increased renal excretion of sodium, bicarbonate, and potassium as a compensatory response to the respiratory alkalosis; salicylate-induced increased permeability of the renal tubules with further loss of potassium; and intracellular accumulation of sodium and water. A final factor is inhibition of the active transport system, secondary to uncoupling of oxidative phosphorylation.

Salicylate related decrease in renal blood flow or direct nephrotoxicity may cause acute non-oliguric renal failure. Drug induced secretion of inappropriate antidiuretic hormone may also affect renal function. The exact mechanism by which salicylates increase alveolar capillary membrane permeability is not clearly defined. Theories include inhibition of prostacyclin, changes in platelet-vessel interaction, and neurogenic influences.

In adults, risk factors for salicylate-induced pulmonary edema include age greater than 30 years old, cigarette smoking, chronic salicylate ingestion, metabolic acidosis, neurologic symptoms, and serum salicylate concentration greater than 40 mg/dL. Risk factors in children include high serum salicylate levels (>80 mg/dL), large anion gap, decreased serum potassium concentration, and low Pco2.

Salicylates severely affect the CNS in two ways. First, there is, a poorly elucidated aspect of toxicity that ultimately results in cerebral edema. This pathway is presumably related to increased energy requirements, acidemia, and direct cellular toxicity. Second, the consumption of glucose in the brain may outpace the supply. This occurs even in the face of normal serum glucose. One or both
of these mechanisms cause altered mental status, seizures, and coma.

At a moderate to high tissue burden, salicylates induce a classic finding of salicylate toxicity—tinnitus, or the sensation of ringing in the ears. This phenomenon is due to a combination of central and peripheral effects. Cochlear toxicity is thought to be the result of alterations in N-methyl-D-aspartate (NMDA) activity, decreased blood flow, and increased membrane permeability. Cochlear toxicity combines with hyperactivity in the auditory cortex to cause tonotopic shifts where upper and lower frequency sounds are perceived in the 10 to 20 hertz tinnitus range, and sounds within this range become hyperacute. Salicylate induced hearing disturbance may take days to resolve after the tissue burden normalizes.4,5

Physiologic changes of aging predispose elderly patients to toxicity from chronic therapeutic ingestion. Decreased liver blood flow limits biotransformation of salicylate, and decreased renal function reduces salicylate clearance. Chronic ingestion decreases albumin binding, increasing the free salicylate that can enter the cell, and allows salicylates more time to pass through the blood–brain barrier. A patient with chronic salicylate toxicity and a serum concentration of 40 mg/dL may be more ill than a patient with an acute ingestion and serum concentration of 80 mg/dL.

Clinical Features
Salicylate toxicity initially generates GI distress followed by tachypnea, tinnitus, and hearing disturbance due to concentration dependent reversible otoxicity, diaphoresis, and an evolving anion gap acidosis. As the toxicity progresses, hyperthermia, coagulopathy, cerebral and pulmonary edema, cardiovascular collapse, and, ultimately, death occur. Chronic poisoning may be much more subtle, manifesting as a waxing and waning combination of the above features of toxicity.3

Differential Diagnoses
Salicylism mimics sepsis, CNS infection, withdrawal syndromes, and alcoholic or diabetic ketoacidosis. This is especially true in chronic toxicity given that the serum salicylate concentration is relatively low. Thus, the severity of poisoning is often not recognized or not fully appreciated. In addition, co-ingestion is common, so evaluation for other toxic exposures is warranted.

Other pain relievers and fever reducers such as acetaminophen and ibuprofen are often confused with aspirin by patients. Other toxins that cause a metabolic acidosis with an elevated anion gap include colchicine, iron, isoniazid, methanol, ethylene glycol, and cyanide.

Diagnostic Testing
The serum salicylate concentration, acid-base status, and potassium are key diagnostic studies. Be mindful of units when interpreting salicylate levels. Serum salicylate concentrations are reported as mg/dL, mg/L, or mmol/L by various labs but are listed in mg/dL in this text. The Done nomogram should not be used to determine prognosis or treatment of the salicylate-poisoned patient. Measure a salicylate concentration on arrival with a second sample obtained 2 hours later if the first level is detectable. If the second concentration is not substantially declining, obtain concentrations every 2 hours to monitor for continued absorption, which may be prolonged. Serum salicylate levels should be repeated every 2 hours until three consecutive levels are both <30 mg/dL and are decreasing by at least 10% to 20% on each measurement while no longer undergoing therapy to enhance elimination. Even in the face of an initial undetectable level, if the history suggests significant salicylate ingestion, then a second level should be performed 2 hours later to ensure that delayed absorption is not occurring.4,5

Acid-base status can change quickly, and monitoring of pH every 2 hours is important to guide treatment. Use early and frequent blood gas determinations in symptomatic patients to rapidly assess acid-base and compensatory status. Developing acidemia portends severe disease. The pH begins to drop when the patient is unable to compensate for acidemia. Lactic acid accumulates, and serum bicarbonate is consumed. When serum pH is less than 7.4 and both PaCO₂ and bicarbonate level are low, hemodynamic instability rapidly develops.4

A metabolic panel is necessary to guide electrolyte replacement (focused on potassium) and to assess renal function and glucose metabolism. However, anion gap determination on a metabolic panel is not a substitute for obtaining a salicylate level or measuring pH. A serum acetaminophen concentration should also be obtained to screen for ingestion of this common, clinically occult analgesic. An electrocardiogram (ECG) is indicated in older patients with underlying cardiac disease that are on daily aspirin therapy.

Management
Stabilization and Supportive Care
Accurate ascertainment of vital signs is the initial step in assessment, including oxygen saturation, respiratory rate, and a reliable temperature. Chest auscultation provides evidence of pulmonary edema, and altered mental status may suggest CNS toxicity.

Dehydration occurs early in salicylate intoxication because of the hypermetabolic state and initial fluid requirements may be as high as 4 to 6 L. Fluid administration should be guided by the patient’s apparent deficit to maintain urine output of 2 to 3 mL/kg/hr. Correct potassium depletion to maintain a serum level greater than 4.5 mEq/L.5

Unless the patient is decompensating, early mechanical ventilation should be avoided. Similar to diabetic ketoacidosis, it is difficult to artificially achieve adequate minute ventilation that sufficiently matches the patient’s own respiratory compensation. In addition, the loss of ventilation during the intubation results in rapid loss of respiratory compensation and worsening acidemia. If the patient is sufficiently critically ill to require intubation, worsening of acidosis during apnea is potentially harmful. Thus we recommend administration of 50 to 100 mEq (1 to 2 amps) of sodium bicarbonate (NaHCO₃) immediately prior to the procedure irrespective of the serum pH. Attempt to adjust the tidal volume post-intubation to match the pre-intubation PaCO₂ level. In addition, establish an elevated minute volume and obtain

---

**BOX 144.1**

**Acid Base Disturbance and Progression of Toxicity in Acute Salicylate Overdose**

Early (0 to 4 hours; level 20 to 60 mg/dL): Respiratory alkalosis with alkaluria; gastrointestinal (GI) distress, mild to moderate hyperpnea, tinnitus, lethargy
Moderate (2 to 12 hours; level 50 to 90 mg/dL): Respiratory alkalosis and metabolic acidosis with alkaluria or neutral pH; severe hyperpnea, lethargy or agitation, hyperthermia
Severe (6 to 24 hours; Level >80 mg/dL): Respiratory alkalosis or acidosis and metabolic acidosis with acidemia; severe hyperpnea, coma or acute delirium, hyperthermia, pulmonary or cerebral edema, seizure, cardiovascular collapse
frequent blood gases to guide ventilator management to maintain respiratory compensation.1

Decontamination

Activated charcoal (AC) has been shown to reduce salicylate absorption in both animal studies and human volunteer trials. Evidence in overdose is less clear. We recommend administering multiple-dose oral AC (25 to 50 gm) every 2 to 4 hours if the patient’s GI, mental, and hemodynamic status tolerate, because large salicylate ingestions tend to form gastric concretions. AC is not used in chronic salicylate poisoning because the presentation occurs long after absorption.

Enhanced Elimination

Specific treatment of salicylate toxicity has two objectives: (1) to correct fluid deficits and acid-base abnormalities and (2) to increase excretion (Box 144.2).

Because salicylates have a low \( pK_a \) and are renally excreted, alkaline urine traps the salicylate ion and increases excretion. Urine alkalinization is advisable in patients with salicylate levels greater than 30 mg/dL, significant acid-base disturbance, or increasing salicylate levels. This is most often achieved via administration of a bicarbonate drip: 132 to 150 mEq (three 50 mL ampules) of 7.5% or 8.4% \( \text{NaHCO}_3 \) in 1 L of dextrose 5% in water (D5W) + 40 mEq of potassium chloride (KCl) running at 2 to 3 mL/kg/hr. Salicylate clearance varies in direct proportion to flow rate but increases exponentially with pH. A urine pH of at least 7.5 to 8.0 is ideal to increase excretion. Urine alkalinization is difficult to achieve because the excretion of salicylic acid in the urine decreases urine pH. In addition, potassium depletion must be corrected to attain alkaline urine as the kidney exchanges hydrogen for potassium in the setting of hypokalemia, further acidifying the urine. In most patients, a serum pH of up to 7.55 is well tolerated. Forced diuresis should not be performed, because it does not significantly increase salicylate excretion and may potentiate cerebral and pulmonary edema.2,5,6

Hemodialysis is highly effective in resolving salicylate toxicity. It is indicated for patients with any of the following: serum salicylate levels greater than 100 mg/dL in acute and 40 mg/dL in chronic salicylate poisoning; altered mental status, including coma; seizure; endotracheal intubation (other than for co-ingestions); renal or hepatic failure; pulmonary edema; severe acid-base imbalance (pH <7.1 to 7.2); rapidly rising serum salicylate level; and failure to respond to more conservative treatment. Of note, the levels recommended here are for initiation of hemodialysis. Consultation with nephrology to prepare for hemodialysis should occur long prior to reaching a serum salicylate concentration of 100 mg/dL. A concentration of 80 mg/dL, or even lower if concentrations are rising rapidly, should prompt nephrology consultation or transfer to a higher level of care in anticipation of hemodialysis.3

Greater salicylate concentration on the fetal side of the placenta and relative fetal acidemia contribute to fetal distress from maternal salicylate poisoning. Salicylate poisoning during pregnancy is associated with fetal demise, and consultation with an obstetrician to facilitate delivery of the distressed fetus in the third trimester of pregnancy should be considered if the fetus is viable.

Antidote Therapy

Central hypoglycemia may be responsible for altered mental status in the setting of salicylate toxicity. In all cases of altered mental status, even in the face of a normal serum glucose measurement, supplemental intravenous (IV) glucose (0.5 to 1 gm/kg) should be administered. Additional glucose supplementation may be required and should be administered in response to recurrent altered mental status.7

Disposition

In patients with acute intoxication, hospital admission to an intensive care setting is appropriate for pulmonary edema, CNS symptoms (other than tinnitus), seizures, pH <7.3, electrolyte disorders, dehydration, renal insufficiency, or increasing serum levels during serial testing. In patients with chronic intoxication, low serum salicylate concentrations (40 mg/dL) may accompany severe salicylism. These patients should be admitted to a monitored setting for observation, serial levels, and metabolic assessment. Consultation with a medical toxicologist may allow for emergency department (ED) observation management of the salicylate poisoned patient not requiring hemodialysis.

In patients with acute ingestion, repeated serum salicylate measurement is essential to determine that the serum concentration is decreasing before the patient is discharged. Serum salicylate levels should be repeated every 2 hours until three consecutive levels are both <30 mg/dL and are decreasing by at least 10% to 20% on each measurement while no longer undergoing therapy to enhance elimination. In addition, the patient should no longer be symptomatic at the time of discharge. With any case of intentional overdose, psychiatric evaluation is recommended.2,3

NONSTEROIDAL AGENTS

Principles of Toxicity

The nonsteroidal antiinflammatory drugs (NSAIDs) have analgesic, antiinflammatory, and antipyretic activities. Ibuprofen and

**BOX 144.2**

**Treatment of Acute Salicylate Poisoning**

Treat dehydration; maintain urine output at 2 to 3 mL/kg/hr. Correct potassium depletion with goal serum level of 4.5 mEq/L. Consider activated charcoal (AC); 25 grams every 2 to 4 hours for two to four doses if tolerated. Alkalize urine with goal urine pH of 7.5 to 8.0. Infuse bicarbonate drip: 132 to 150 mEq (three 50 mL ampules) of 7.5% or 8.4% NaHCO3 in 1 L of dextrose 5% in water (D5W) + 40 mEq of potassium chloride (KCl) running at 2 to 3 mL/kg/hr. Allow serum pH up to 7.55. Do not attempt forced diuresis.

Initiate hemodialysis if any of the following occur:
- Altered mental status, coma, seizure
- Renal failure
- Hepatic failure
- Pulmonary edema or respiratory failure
- Severe acid-base imbalance (pH <7.1 to 7.2)
- Deterioration in condition
- Intubation
- Failure of urine alkalinization
- Rapidly rising salicylate level
- Serum salicylate concentration ≥100 mg/dL after acute ingestion
- Serum salicylate concentration ≥40 mg/dL after chronic ingestion

Administer intravenous (IV) dextrose 0.5 to 1 g/kg IV for any central nervous system (CNS) abnormalities (altered mental status, coma, agitation, seizure)
naproxen, both propionic acid derivatives, are available over the counter in the United States and are the most commonly encountered NSAIDs. The therapeutic antiinflammatory effect of the NSAIDs is achieved by inhibition of cyclooxygenase (COX) and consequent blockade of prostaglandin production.

NSAIDs are almost completely absorbed from the upper small intestine after oral administration. NSAIDs are highly bound to plasma proteins and therefore have small volumes of distribution (0.10 to 0.17 L/kg). They are eliminated by hepatic biotransformation. Metabolites are typically inactive with the notable exception of phenylbutazone. Plasma half-lives are short (1 to 4 hours), except for naproxen (12 to 15 hours), oxaprozin (25 to 30 hours), piroxicam (45 hours), and phenylbutazone (30 to 100 hours). Elimination half-lives are not substantially prolonged in overdose.

Clinical Features

Most NSAID overdoses are asymptomatic or cause only minor symptoms. Ibuprofen is the most common NSAID ingested in overdose and most follow a benign, self-limited course. Symptomatic overdose occurs only after ingestion of at least 100 mg/kg, and symptoms develop within 4 hours of ingestion. Life-threatening toxicity is rare with most cases limited to mild GI disturbance that resolves in hours. Less common clinical effects include metabolic acidosis, muscle fasciculations, mydriasis, diaphoresis, hyperventilation, bradycardia, hypotension, dyspnea, tinnitus, and rash. Rare cases of coma, seizure, hypotension, and metabolic acidosis have been reported in massive overdoses (400 to 500 mg/kg).

Renal dysfunction is seen only after large acute overdose and in association with a period of relative hypovolemia with hypotension. It is reversible and usually responds to supportive measures.

All propionic acid derivatives have been associated with sporadic cases of aseptic meningitis. This complication is most common with ibuprofen. It occurs in an idiosyncratic fashion—both in overdose and with therapeutic dosing.

Mefenamic acid, a fenamate, is associated with a relatively high incidence of seizures, which occur 2 to 7 hours after supratherapeutic ingestion. Rapid recovery is the rule with supportive care and IV benzodiazepines.

Phenylbutazone, a pyrazolone, is now rarely used because of its association with aplastic anemia and agranulocytosis. Although phenylbutazone overdose is rare, the course is much more severe than with other NSAIDs. Severely poisoned patients have early onset of GI distress, coma, seizure, hyperthermia, hyperventilation, alkalosis or acidosis, hypotension, electrocardiographic abnormalities, or cardiac arrest. Late sequelae of severe poisoning (2 to 7 days) include renal, hepatic, and hematologic dysfunction. The clinical course is prolonged compared with that of other NSAID poisoning, reflecting the elimination half-lives of phenylbutazone and its principal metabolite, oxyphenbutazone.

Differential Diagnoses

Given that nearly all NSAID overdoses are minimally symptomatic, the differential diagnosis should focus on toxicity due to possible co-ingestions. Patients often confuse NSAIDs with other pain relievers and fever reducers, including acetaminophen and salicylates.

Diagnostic Testing

Plasma NSAID concentrations are not clinically useful and are rarely available in the ED. With larger overdoses (>100 mg/kg), a complete blood count, metabolic profile, and assessment of renal function are recommended. Because patients often confuse and mix pain relievers, a screening serum acetaminophen and salicylate level is prudent.

Management

Stabilization and Supportive Care

The management of NSAID overdose is supportive, and there is no specific antidote. Pyrazolone (eg, phenylbutazone) and fenamate (eg, mefenamic acid) toxicity is associated with significantly higher morbidity (see earlier) and may require more supportive care measures, including control of seizures with benzodiazepines, fluid resuscitation, correction of electrolyte disturbances, and ventilatory support. Hypotension is managed with a 1 to 2 L bolus of normal saline or lactated Ringer’s solution, which may be repeated or supported by infusions at two to three times maintenance rate. If perfusion compromise persists, initiate a vasopressor, such as norepinephrine, and titrate to maintain an adequate mean arterial pressure for perfusion. Although it is rarely indicated and not studied, extracorporeal membrane oxygenation has successfully managed refractory hypotension after massive ibuprofen overdose.

Decontamination

There is no evidence supporting the use of gastric emptying or AC in NSAID overdoses.

Enhanced Elimination

Because of high protein binding and rapid metabolism, enhanced elimination is not useful in most cases. In the rare case of a massive overdose with pH <7.1, hemodialysis should be considered to correct acidemia. In this situation, hemodialysis may also remove the free drug once protein binding is overwhelmed. Plasmapheresis has been attempted in severe phenylbutazone poisoning.

Antidote Therapy

There is no specific antidote for NSAID poisoning.

Disposition

Patients who are mildly symptomatic or asymptomatic for more than 4 hours after an NSAID overdose do not require further medical care. Patients who have ingested a pyrazolone or fenamate require observation for possible seizures until 8 hours after ingestion. Those with CNS symptoms, acidosis, or renal insufficiency and who require supportive care should be admitted for ongoing treatment. Patients with mild to moderate symptoms may be observed in the ED until they are asymptomatic or improving. Patients for whom the ingestion represents a suicidal gesture should undergo psychiatric assessment.
Salicylates are profoundly toxic and can be fatal. Salicylate overdose requires active assessment and treatment. The other NSAIDs generally have self-limited toxicity and respond to supportive measures only. There is no antidote for any of these drugs.

- Salicylism should be considered in the differential diagnosis of altered mental status in the elderly.
- Acidity signifies loss of respiratory compensation and acceleration of toxicity.
- The Done nomogram should not be used in the evaluation and treatment of salicylate toxicity.
- Salicylate concentrations and blood gas draws should occur every 2 hours until salicylate level is less than 30 mg/dL and is falling at least 10% between assays in the absence of measures to enhance elimination.
- Potassium stores are rapidly depleted in patients with salicylate intoxication and should be repleted with a goal serum level of 4.5 mEq/L.
- Mechanical ventilation should be avoided if possible in cases of severe salicylate poisoning. Acidosis may rapidly worsen due to loss of ventilation during the intubation procedure, and it is difficult to maintain ventilation at the level of physiological hyperventilation.
- If intubation is necessary, a bolus of sodium bicarbonate (50 to 100 mEq) is given before intubation and post-intubation minute ventilation is increased to match pre-intubation respiratory compensation.
- Enhanced elimination through urinary alkalinization with a sodium bicarbonate drip should be initiated in acute toxicity with a level >30 mg/dL.
- Consultation with nephrology and preparation for hemodialysis should occur if the salicylate concentration is 80 mg/dL or is rising rapidly.
- Hemodialysis is recommended for signs of pulmonary or cerebral edema, coma, seizures, hepatic failure, renal failure, circulatory collapse, or refractory acidosis along with acute levels greater than 100 mg/dL and chronic levels of 40 mg/dL.
- Altered mental status in the setting of salicylate toxicity warrants IV glucose supplementation.
- Most NSAID overdoses are asymptomatic or cause only minor symptoms.
- Ibuprofen, along with other propionic acid derivatives, has been associated with sporadic cases of aseptic meningitis.
- The management of NSAID overdose is supportive, and there is no specific antidote. Hemodialysis is reserved for patients with massive overdose and pH <7.1.
- Patients who have ingested a pyrazolone or fenamate require observation for possible seizures until 8 hours after ingestion.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
144.1. What type of acid-base disorder is caused by salicylate overdose?
A. Metabolic acidosis and respiratory acidosis
B. Metabolic acidosis and respiratory alkalosis
C. Metabolic alkalosis and respiratory acidosis
D. Metabolic alkalosis and respiratory alkalosis
E. No acid-base disorder

Answer: B. Early in overdose, salicylates stimulate the respiratory center, causing hyperventilation and a respiratory alkalosis. Later, salicylates inhibit mitochondrial oxidative phosphorylation, resulting in anaerobic metabolism and a metabolic acidosis. This is the classic situation but is later followed by respiratory compensation, resulting in the possibility of a triple acid-base disorder.

144.2. A 22-year-old man presents 6 hours after a suicide-related aspirin overdose. His only complaint is of tinnitus, and his vital signs and physical examination are normal. His salicylate level is 47 mg/dL. His serum pH is 7.3, with an anion gap of 18 and a serum bicarbonate level of 17 mmol/L. Which of the following is the most appropriate therapy?
A. Forced diuresis
B. Hemodialysis
C. Observation only
D. Oral-activated charcoal due to chronic poisoning
E. Urinary alkalinization

Answer: E. Salicylates are acidic compounds and therefore readily ionize in an alkaline environment. Only in the non-ionized state can they traverse cell membranes. Thus, once ionized in the urine, they are effectively “trapped” and can be easily excreted. Urinary alkalinization is indicated in patients with a salicylate level greater than 30 mg/dL, significant acid-base disturbances, or increasing salicylate levels. Forced diuresis does not increase excretion, increases the risk for pulmonary and cerebral edema, and is never indicated. Hemodialysis is the ultimate treatment for salicylate poisoning but is generally reserved for patients with more severe signs or symptoms, more severe acid-base disturbances, or acute salicylate levels greater than 100 mg/dL. Observation alone would be indicated in a patient with a history of salicylate overdose but with no symptoms and normal laboratory values. AC can decrease the amount of salicylate absorbed if given within 1 hour of ingestion. Because large salicylate ingestions tend to form gastric concretions, multiple doses of AC may be indicated. AC is not used in chronic salicylate poisoning because the presentation occurs long after absorption.

144.3. Which of the following patients is at the highest risk of death?
A. A 9-year-old boy with chronic salicylate ingestion and salicylate level of 10 mg/dL
B. A 20-year-old pregnant woman with acute salicylate overdose and salicylate level of 100 mg/dL
C. A 24-year-old man with acute salicylate overdose and salicylate level of 110 mg/dL
D. A 30-year-old woman with chronic salicylate ingestion and salicylate level of 50 mg/dL
E. A 42-year-old woman with acute salicylate overdose and salicylate level of 90 mg/dL

Answer: D. The mortality rate for chronic salicylate ingestion is 25 times that of acute salicylate ingestion. Infants and the elderly, as well as patients with comorbidities, are also at greater risk of death. Salicylate poisoning can cause severe fetal distress and ultimate fetal demise, but the prognosis for the mother is not significantly changed. In otherwise similar patients, a higher salicylate level is associated with a worse prognosis.

144.4. A 41-year-old man presents after an accidental ibuprofen overdose. He complains of epigastric pain, nausea, and one episode of vomiting. He reports that approximately 2 hours ago he took four 200-mg ibuprofen tablets. (He meant to take four 200-mg ibuprofen tablets.) Which of the following is the appropriate next step?
A. Check electrocardiogram (ECG) to determine further treatment
B. Check serum chemistry and salicylate level to determine further treatment
C. Observation for resolution of symptoms
D. Oral activated charcoal (AC)
E. Urinary alkalinization

Answer: C. Nonsteroidal antiinflammatory drugs (NSAIDs) are generally safe in overdose. Specifically, ibuprofen overdose often results in mild self-limited gastrointestinal (GI) upset. Typically, at least 100 mg/kg of ibuprofen needs to be ingested to cause symptoms. Rare, but serious, symptoms include coma, seizure, hypotension, hypothermia, GI bleeding, acute renal failure, and metabolic acidosis. All symptoms are treated with supportive care. Symptoms almost always develop within 4 hours of ingestion. In general, patients may be discharged in cases of small overdoses (<100 mg/kg), once symptoms resolve or after a 4-hour period of observation.
Anticholinergic agents cause toxicity through inhibition of muscarinic, nicotinic, parasympathetic, or sympathetic acetylcholine receptors. Nicotinic receptor inhibition and ganglionic acetylcholine inhibition at parasympathetic and sympathetic locations is covered in Chapter 157. This chapter focuses on antimuscarinic effects and toxicity. The terms anticholinergic and antimuscarinic are commonly used synonymously, but the mechanism of toxicity is more accurately described by the term antimuscarinic, and thus that term is used in this chapter.

Antimuscarinic effects are due to inhibition of acetylcholine at muscarinic receptors. Muscarinic receptors are found on peripheral postganglionic cholinergic nerves in smooth muscle (intestinal, bronchial, and cardiac), the secretory glands (salivary and sweat), the ciliary body of the eye, and the central nervous system (CNS).

Antimuscarinic agents have been used medicinally from antiquity to present day. Mandrake plant remains were found in the casket of Tutankhamen, the Old Testament of the Bible references use as an aphrodisiac, and antimuscarinic plants were used as anesthetics in Greek and Roman settlements in the first century. Atropine, hyoscyamine, and scopolamine are naturally occurring tertiary amine antimuscarinic agents that remain in wide clinical use today. The tertiary amine structure allows the agent to cross the blood-brain barrier; and therefore, these agents may precipitate CNS toxicity. Quaternary amine antimuscarinic agents, such as glycopyrrolate, have been developed to mitigate CNS side effects due to their limited ability to cross the blood-brain barrier, although mild delirium may occur in the setting of a large overdose.

Clinical Features

Over 600 compounds contain antimuscarinic activity, including prescription drugs, over-the-counter medications, and plants. The effects of muscarinic receptor blockade are used for clinical purposes including pupillary dilation, antispasmodics, treatment of motion sickness, drying of airway secretions, reactive airways disease, treatment of bradycardia, treatment of Parkinsonism, and the management of urinary incontinence and bladder spasm. The agents that most commonly precipitate antimuscarinic toxicity, such as H1 antihistamines and some antipsychotics, often affect several neurotransmitters and receptor systems in addition to antagonism at muscarinic receptors. This may complicate the clinical presentation, and some clinical symptoms may be unique to the specific etiologic agent (Table 145.1).

Antimuscarinic toxicity has central and peripheral manifestations (Fig. 145.1 and Box 145.1). Peripheral muscarinic antagonism causes tachycardia, hypertension, hyperthermia, mydriasis, dry mouth, dry skin (lack of sweating), skin flushing, decreased bowel motility, and urinary retention. CNS blockade of muscarinic receptors may produce delirium characterized by confusion, mumbling speech, agitation, hallucinations, picking gestures, myoclonus, tremor, and coma. Seizures are not expected from pure muscarinic receptor antagonism but many antimuscarinic medications have activity at other receptors that may precipitate seizures. Diphenhydramine toxicity is a classic example of this; it causes significant antimuscarinic symptoms and may also cause seizures through sodium channel blockade. Manifestations of the toxidrome are frequently incomplete and either peripheral or central components may predominate depending upon the antimuscarinic agent, the dose, and the individual patient (see Table 145.1). Only about one-third of patients will manifest all three classic autonomic findings: tachycardia, dry skin/axilla, and mydriasis. Patients may demonstrate delirium as their only manifestation of toxicity. The duration of toxicity is dependent on the dose and is difficult to predict but is often prolonged (18 to 72 hours) due to delayed gastric emptying.

Differential Diagnoses

The diagnosis of antimuscarinic poisoning is most often made by obtaining a history of exposure, either from the patient or someone who was present with the patient at the time. Antimuscarinic toxicity is an important consideration when there is altered mental status with a history of exposure or if physical examination is consistent with toxicity (Box 145.2). Altered mental status, mydriasis, and tachycardia are common antimuscarinic effects that are also seen with multiple conditions (eg, sympathomimetic toxicity, serotonin syndrome, alcohol withdrawal). However, dry axilla, decreased bowel sounds, and urinary retention are less common with adrenergic toxicity and more likely to be associated with antimuscarinic causes. Agitation occurs both with sympathomimetic and antimuscarinic toxicity, but severe agitation and combativeness are more likely to represent the sympathomimetic than antimuscarinic agents—the latter generally cause only mild to moderate agitation. Major medical emergencies should be considered early in the course to ensure timely management. Intracranial hemorrhage (ICH) may lead to altered mental status, hypertension, and dilated pupils, although unilateral pupillary dilation is more likely due to tonsillar herniation when ICH is the etiology of altered mental status. CNS infections or hyperthyroidism may similarly lead to altered mental status, hyperthermia, and hypertension. Failure of physostigmine to reverse the altered mental status should prompt evaluation for meningitis, encephalitis, and thyrotoxicosis.

Diagnostic Testing

Laboratory

Patients with mild toxicity, a reliable history of exposure, and symptoms consistent with antimuscarinic toxicity do not require specific laboratory testing. Patients with an unclear history of exposure, other potential etiologies, moderate to severe toxicity, or hyperthermia should be evaluated for causes of altered mental status and end-organ toxicity, including serum glucose,

SODIUM BICARBONATE BOLUS (50 mEq) should be given for evidence of sodium channel blockade with a QRS interval of more than 120 msec, and it may be repeated with a goal of QRS duration of less than 110 msec. Patients with recurrent seizures or agitation that place the patient or staff at risk should be treated with lorazepam (0.05 to 0.1 mg/kg), midazolam (0.05 to 0.1 mg/kg), or diazepam (0.1 to 0.2 mg/kg) boluses. These doses may be repeated every 5 to 15 minutes as needed to halt seizures and provide adequate sedation. When seizures are not present and agitation requires intervention, physostigmine treatment, which is both diagnostic and therapeutic, is preferred (see later discussion). Patients with drug-induced hyperthermia should be promptly treated to prevent progressive acidosis and subsequent organ failure. If evaporative cooling measures and sedation fail, progression to paralysis, ventilation, and airway control is necessary. The target temperature is 36° to 38° C.

Decontamination

Most patients with antimuscarinic poisoning do well with symptomatic care alone. There is no role for gastric lavage, whole bowel irrigation, or hemodialysis. Oral activated charcoal, similarly, is not indicated for the vast majority of antimuscarinic poisoned patients. However, oral activated charcoal may be used for symptomatic patients who have ingested a highly toxic quantity of antimuscarinic plant seeds only if the patient presents early after ingestion (<2 hours) and is anticipated to remain cooperative. Administering AC after antidote treatment with physostigmine has reversed delirium is a complex decision and is best made in consultation with a medical toxicologist or regional poison center.

Pharmacologic Intervention and Antidote Treatment

Control of delirium is the most common reason for emergency intervention in antimuscarinic poisoned patients. Sedation or antitodal treatment is indicated for patients whose delirium places them at risk of harming themselves or staff, requiring ongoing physical restraint, or interfering with effective treatment (eg, pulling out IV lines). Physostigmine is the preferred for treatment for antimuscarinic toxicity if no contraindications are present.

Physostigmine salicylate is a specific antidote for antimuscarinic toxicity (Box 145.3).

Physostigmine is safe and highly effective in reversing both agitation and delirium when used as treatment of delirium caused by antimuscarinic poisoning. In this specific setting, physostigmine is several-fold more effective than benzodiazepines, which control agitation in only about one-quarter of patients and have

**Antimuscarinic Reversal Agent: Physostigmine**

**PHYSOSTIGMINE SALICYLATE**

Indications: Diagnosis and treatment of antimuscarinic toxicity.
Contraindications: Narrow angle glaucoma, first degree atrioventricular (AV) blockade, bradycardia, and seizures due to current overdose.
Adverse effects: Bradycardia, seizure, vomiting.
Route: Intravenous (IV) or intramuscular (IM).
Kinetics/dynamics: Time of onset within 5 minutes following IV administration; 20 to 30 minutes following IM administration.
Half-life: 16 ±3 minutes. Plasma cholinesterase inhibition 84 ±5 minutes.
Dosing: 1 to 2 mg bolus slowly (no faster than 1 mg/min). A drip (gtt) may be used. Start gtt at 1 mg/hour titrated every 30 minutes to effect.

**Electrocardiogram**

An electrocardiogram (ECG) should be obtained in cases of suspected tricyclic antidepressant (TCA) or diphenhydramine toxicity to assess for possible sodium channel blockade (widened QRS interval or terminal R wave in lead AvR >3 mm). Presence of bradycardia or atrioventricular (AV) block contraindicates the use of physostigmine.

**MANAGEMENT**

**Stabilization**

Initial management should focus on evaluation and stabilization of cardiovascular and neurologic toxicity. An intravenous (IV) sodium bicarbonate bolus (50 mEq) should be given for evidence of sodium channel blockade with a QRS interval of more than 120 msec, and it may be repeated with a goal of QRS duration of less than 110 msec. Patients with recurrent seizures or agitation that place the patient or staff at risk should be treated with lorazepam (0.05 to 0.1 mg/kg), midazolam (0.05 to 0.1 mg/kg), or diazepam (0.1 to 0.2 mg/kg) boluses. These doses may be repeated every 5 to 15 minutes as needed to halt seizures and provide adequate sedation. When seizures are not present and agitation requires intervention, physostigmine treatment, which is both diagnostic and therapeutic, is preferred (see later discussion). Patients with drug-induced hyperthermia should be promptly treated to prevent progressive acidosis and subsequent organ failure. If evaporative cooling measures and sedation fail, progression to paralysis, ventilation, and airway control is necessary. The target temperature is 36° to 38° C.

Decontamination

Most patients with antimuscarinic poisoning do well with symptomatic care alone. There is no role for gastric lavage, whole bowel irrigation, or hemodialysis. Oral activated charcoal, similarly, is not indicated for the vast majority of antimuscarinic poisoned patients. However, oral activated charcoal may be used for symptomatic patients who have ingested a highly toxic quantity of antimuscarinic plant seeds only if the patient presents early after ingestion (<2 hours) and is anticipated to remain cooperative. Administering AC after antidote treatment with physostigmine has reversed delirium is a complex decision and is best made in consultation with a medical toxicologist or regional poison center.

Pharmacologic Intervention and Antidote Treatment

Control of delirium is the most common reason for emergency intervention in antimuscarinic poisoned patients. Sedation or antitodal treatment is indicated for patients whose delirium places them at risk of harming themselves or staff, requiring ongoing physical restraint, or interfering with effective treatment (eg, pulling out IV lines). Physostigmine is the preferred for treatment for antimuscarinic toxicity if no contraindications are present.

Physostigmine salicylate is a specific antidote for antimuscarinic toxicity (Box 145.3).

Physostigmine is safe and highly effective in reversing both agitation and delirium when used as treatment of delirium caused by antimuscarinic poisoning. In this specific setting, physostigmine is several-fold more effective than benzodiazepines, which control agitation in only about one-quarter of patients and have
no effect on delirium. Physostigmine use also seems to hasten recovery from the manifestations of antimuscarinic toxicity. Therefore physostigmine should be used early in the course of suspected antimuscarinic poisoning, because it is a more effective treatment of agitation and delirium and may limit additional unnecessary diagnostic testing and sedative requirements.

The drug is a tertiary amine carbamate that reversibly inhibits cholinesterases in the both peripheral nervous system and CNS. This allows for acetylcholine accumulation and subsequent competition with the antimuscarinic blocking agent occupying the receptor. Physostigmine has a short half-life, approximately 20 minutes. Although inhibition of the esterase, which yields the pharmacodynamic effects, last considerably longer with a half-life of 80 minutes. Accordingly, the clinical duration of physostigmine is 3 to 6 hours.

Physostigmine should be used to control symptoms of agitation or delirium potentially attributable to antimuscarinic toxicity. The initial dose of physostigmine is 1 to 2 mg IV over 5 minutes (see Box 145.3). If only a partial response is observed (the delirium is not completely reversed) at 10 minutes post administration, the same dose may be repeated. If agitation or delirium symptoms recur within 3 hours and the patient is again a risk to themselves or staff, repeat dosing of 1 to 2 mg IV over 5 minutes should be given.4 If three or more administrations are necessary over a 6-hour period to control agitation or delirium, then an infusion should be started. A bolus of 1 to 2 mg IV should be given and the infusion started at 1 mg/hour.5,6 If symptoms recur while on the infusion, the drip can be increased by 0.5 mg/hour every hour to maintain a normal mental status. The patient should be placed on a cardiac monitor to monitor for bradycardia during physostigmine administration. The infusion should be stopped every 12 hours to determine if the toxidrome has resolved. If symptoms recur during observation off physostigmine, the same bolus and infusion rate should be given. Patients may be considered medically cleared from antimuscarinic toxicity if symptoms do not recur within 6 hours of the last antidote dose.7 If the patient develops side effects (vomiting, diarrhea, or bradycardia), the infusion should be stopped. Extended observation with repeated dosing and/or infusions may be required in very large overdoses or in antimuscarinic plant seed ingestions because ongoing absorption leads to prolonged symptoms.

When used diagnostically, near complete reversal of delirium over a matter of minutes is specific for antimuscarinic poisoning and may be used to defer additional testing, such as lumbar puncture or neuroimaging.8

We do not recommend use of physostigmine in the treatment of acutely TCA poisoned patients with cardiovascular toxicity, specifically bradycardia or AV block. Physostigmine use in this context has been associated with ventricular tachycardia and cardiac arrest. TCAs have inherent cardiac toxicity, so it is not clear that physostigmine actually causes these adverse cardiac events. Many patients who received physostigmine without adverse effects were subsequently found to have ingested a TCA.8 Further considerations regarding the use of physostigmine in patients with TCA toxicity are discussed in Chapter 146.

When physostigmine is contraindicated, sedation can be accomplished with IV benzodiazepines, as described earlier in this chapter.

Overall, physostigmine should be given as a diagnostic and therapeutic intervention, if the antimuscarinic-induced delirium places the patient or staff at risk, in patients without overdose-induced seizure, AV blockade, or bradycardia.

**DISPOSITION**

Most patients do well with supportive care (sedation, hydration, temperature control, and observation). Length of observation and need for admission depend on the agent, the dose, the intent, and the patient. Antimuscarinic agents slow gut motility, which increases the time to peak symptoms. As such, long-acting agents, plant seeds, or large ingestions should have extended observation up to 24 hours even if asymptomatic. Patients at extremes of age are at increased risk for toxicity and should be considered for observation. Patients with an unreliable history or concern for self-harm should have extended observation and psychiatric consultation.

**Observation at Home**

Asymptomatic, accidental exposures to a known, low dose, in patients with normal mental status and normal vital signs four hours after ingestion are safe to be observed at home by a trustworthy adult.

**Emergency Department Observation**

Patients with mild toxicity (normal mental status or slight drowsiness, normal vital signs, no ECG changes) and small ingestions should be observed in the ED until symptoms are clearly resolving (typically less than 6 hours). Patients treated with physostigmine who are asymptomatic 6 hours following physostigmine administration are considered clear of antimuscarinic toxicity and can be medically cleared.1

**Hospital Admission**

Patients with self-harm attempts and moderate to severe toxicity (abnormal vital signs, altered mental status) should have an extended observation period for progression of toxicity or until symptoms improve. Ingestion of large amounts of pills or plant seeds should be expected to require prolonged observation (24 to 48 hours) due to decreased gastrointestinal motility. Patients requiring more than three doses of physostigmine within 6 hours or who require an infusion of physostigmine should be admitted to a monitored setting, because the clinical course is likely to be prolonged.

**Intensive Care Unit Admission**

Patients with agitated delirium requiring physostigmine infusion, hyperthermia, dysrhythmia, or seizures will benefit from intensive care unit (ICU) admission for monitoring, frequent medications, and airway control if high doses of sedatives or additional physostigmine administration are necessary.

**Consultations**

Medical toxicology or poison center consultation should be considered when there are questions about exposure, diagnosis, or the appropriateness of antidotal therapy.
Symptoms of muscarinic receptor blockade may include delirium, mydriasis, a lack of sweating, dry mucous membranes, ileus, urinary retention, hyperthermia, tachycardia, and hypertension.

Delirium may be the sole manifestation of toxicity and only one-third of patients manifest all of the classic autonomic findings of tachycardia, dry skin and axilla, and mydriasis.

Physostigmine should be given to control severe agitation and delirium precipitated by muscarinic receptor antagonism.

Physostigmine is relatively contraindicated in patients with bradycardia or AV block in the setting of possible TCA toxicity.

Benzodiazepines should be used for symptom control when seizures occur or when physostigmine is contraindicated.

Patients who develop hyperthermia despite treatment with evaporative cooling should be paralyzed, intubated, and cooled.

Symptomatic patients should be observed until symptoms are clearly resolving. Accidental ingestions with mild symptoms can be expected to improve in less than 6 hours. Purposeful ingestions with mild to moderate symptoms will require admission to the hospital for extended observation (24 to 48 hours).

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
145.1. A 21-year-old man presents after drinking an "herbal tea" with some friends. He reports visual hallucinations. He has a resting tachycardia and a mildly elevated temperature. On physical examination, he is noted to have dry mucous membranes, dry and flushed skin, and absent bowel sounds. In addition to certain plants, which of the following medications can also cause these symptoms?

A. Amiodarone
B. Clonidine
C. Diphenhydramine
D. Lidocaine
E. Morphine

Answer: C. This patient is experiencing the antimuscarinic toxicity. In addition to the signs and symptoms described here, patients may also have mydriasis and bladder distention. Mental status can be agitated or depressed. Myoclonus or choreoathetoid movements can also be seen. Amiodarone can cause hypothyroidism or hyperthyroidism and skin discoloration, as well as several other long-term effects. Clonidine can cause dry mouth, drowsiness, bradycardia, and hypotension. Lidocaine can cause headaches, dizziness, confusion, tinnitus, and tremor, as well as bradycardia and hypotension. Morphine can cause respiratory cerebral depression, as well as miosis, bradycardia, and hypotension.

145.2. Many signs and symptoms of the antimuscarinic syndrome are similar to those of other syndromes, including the sympathomimetic syndrome, serotonin syndrome, and neuroleptic malignant syndrome. Which of the following antimuscarinic findings is most likely to distinguish the antimuscarinic syndrome from the other syndromes listed?

A. Altered mental status
B. Altered movements
C. Dry skin
D. Fever
E. Mydriasis

Answer: C. All the other syndromes often have some degree of diaphoresis. Fever, altered mental status, and mydriasis can occur in all the named syndromes. Myoclonus can occur in the antimuscarinic syndrome, tremor in the serotonin syndrome, and rigidity in the neuroleptic malignant syndrome.

145.3. A 31-year-old woman presents with altered mental status after ingesting an unknown quantity of an unknown medication. Her vital signs are significant for tachycardia and fever. Her physical examination reveals mydriasis, dry mucous membranes, dry skin, decreased bowel sounds, and hypotension. Her electrocardiogram (ECG) reveals a wide QRS complex and prolonged QT interval. Which of the following medications is associated with this toxidrome?

A. Amitriptyline
B. Dextroamphetamine
C. Diphenhydramine
D. Fluoxetine
E. Lithium

Answer: C. This patient is experiencing many of the signs and symptoms of antimuscarinic syndrome. However, pure antimuscarinic rarely if ever cause cardiac dysrhythmias (other than sinus tachycardia). Tricyclic antidepressants (TCAs) frequently cause antimuscarinic signs and symptoms but also cause dysrhythmias. Although selective serotonin reuptake inhibitors, stimulants, and lithium can all cause similar signs and symptoms, electrocardiographic abnormalities such as those described here are rare.

145.4. Which diagnostic test should be performed in almost all patients presenting with the antimuscarinic syndrome?

A. Arterial blood gas analysis
B. Computed tomography (CT) scan of the brain
C. Electrocardiography
D. Electroencephalography
E. Urine drug screen

Answer: C. Patients with a clear presentation and mild symptoms do not necessarily require any diagnostic evaluation. However, patients with more severe symptoms should have measurements of serum electrolytes, renal function, creatine kinase, and glucose concentration performed. Electrocardiography is most helpful because cyclic antidepressants are a common cause of antimuscarinic symptoms and can cause fatal cardiac dysrhythmias. Arterial blood gas analysis might be helpful if the patient has respiratory depression. Head CT might be indicated in patients with altered mental status of unknown cause. Electroencephalography would be indicated only if there is a suspicion of unrecognized seizures. Urine drug screens are almost never helpful in determining treatment, especially in the case of antimuscarinic syndrome because they will not detect most of the medications responsible for this syndrome.

145.5. What is the best initial treatment of hyperthermia in patients with antimuscarinic syndrome?

A. Acetaminophen
B. Cooling blankets
C. Dantrolene
D. Evaporative cooling
E. Physical restraints

Answer: D. Evaporative cooling is the most effective and noninvasive way to decrease temperature. Death has occurred because of untreated hyperthermia in patients with antimuscarinic syndrome. Antipyretics such as acetaminophen are ineffective at reducing temperature because hyperthermia is not “fever.” Dantrolene is useful in malignant hyperthermia but has no role in hyperthermia of other causes. Cooling blankets are ineffective. Physical restraints are likely to worsen the problem and to increase the risk of rhabdomyolysis and myoglobinuric renal failure. If a patient is dangerously agitated, physostigmine are the agents of choice to decrease agitation, muscle activity, and related metabolic activity that contribute to hyperthermia.

REFERENCES

145.6. Which of the following medications crosses the blood-brain barrier and is potentially useful in the treatment of antimuscarinic syndrome?
   A. Edrophonium
   B. Metoclopramide
   C. Neostigmine
   D. Physostigmine
   E. Pyridostigmine

   **Answer:** D. Metoclopramide is an antiemetic and prokinetic medication that has no role in antimuscarinic syndrome. All of the other agents are acetylcholinesterase inhibitors, but only physostigmine crosses the blood-brain barrier and so it is the only drug that can reverse the central and peripheral effects of antimuscarinic medications. However, physostigmine can cause serious side effects and thus should be used carefully in patients with bradycardia and A-V block.

145.7. Which of the following is a contraindication to physostigmine use in a patient with antimuscarinic syndrome?
   A. Altered mental status
   B. Bradycardia and atrioventricular (A-V) blockade
   C. Coexisting myasthenia gravis
   D. Hyperthermia
   E. Seizure

   **Answer:** B. Physostigmine is an acetylcholinesterase inhibitor that is useful to reverse the effects of antimuscarinic medications. However, it is contradicted with narrow angle glaucoma, A-V blockade, bradycardia, and seizures due to the causal overdose. The main benefit of physostigmine is to reverse the altered mental status and agitation caused by the antimuscarinic medication. Physostigmine is occasionally used to treat myasthenia gravis. Hyperthermia and seizures can occur as part of the antimuscarinic syndrome, and although neither is directly treated with physostigmine, they are not contraindications to its use.
CHAPTER 146
Antidepressants

Michael D. Levine | Anne-Michelle Ruha

PRINCIPLES OF TOXICITY

Depression is one of the most common medical conditions in the United States, with a lifetime prevalence of nearly 20%.

Whereas many treatment strategies are used in the management of depressed patients, pharmacotherapy remains a cornerstone of modern practice. Modern antidepressant therapy hinges on the 60-year-old monoamine hypothesis, which suggests that depressive symptoms are mediated through an imbalance of the dopaminergic, noradrenergic, and serotonergic systems.

As a result, numerous antidepressant classes have emerged in an attempt to increase synaptic monoamine concentrations.

In the early 1950s, isoniazid and iproniazid were introduced for the treatment of tuberculosis. Shortly after, it was noted that these patients had improved mood, which was attributed to the ability of iproniazid to inhibit monoamine oxidase (MAO). Iproniazid, a derivative of isocarboxazid, subsequently became the first drug marketed specifically as an antidepressant.2-3 This led to the advent of other monoamine oxidase inhibitors (MAOIs). In 1956, the antidepressant effect of imipramine, a tricyclic agent, was recognized, and it was marketed the following year. The MAOIs and tricyclic antidepressants (TCAs) became the mainstay for treatment of depression for several decades until the advent of the safer selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs).

The morbidity of antidepressants in overdose varies greatly by specific class. Overall, however, there were nearly 110,000 overdoses on antidepressants reported to United States poison control centers in 2013. Despite representing only 4% of calls, they accounted for 9% of fatalities.

MONOAMINE OXIDASE INHIBITORS

MAO is located on the outer mitochondrial membrane and is responsible for breakdown of cytoplasmic catecholamines. Monoamine oxidase type A (MAO-A) primarily deaminates serotonin and norepinephrine; monoamine oxidase type B (MAO-B) primarily deaminates phenylethylamine.4-6 Tyramine and dopamine are metabolized equally by both isoenzymes.4-6 Whereas most tissues contain both isozymes, MAO-A is primarily found in the placenta, sympathetic nerve terminals, and intestinal mucosa; MAO-B is found primarily in platelets and the basal ganglia.

Drugs targeting the MAO system can act as specific or nonspecific inhibitors. The first-generation MAOIs are nonspecific and irreversible. Drugs belonging to this class include phenelzine, isocarboxazid, and tranylcypromine. The second-generation MAOIs can preferentially inhibit either MAO-A or MAO-B.

MAOIs have fallen out of favor for treatment of depression due to side effects from adverse drug and food interactions. However, their use in treatment of Parkinson’s disease is increasing. Drugs that selectively inhibit MAO-B disproportionately increase dopamine concentrations in the striatum.6 Selegiline is an irreversible MAO-B inhibitor used in the treatment of Parkinson’s disease. Importantly, the selectivity for MAO-B is only present at low doses.7 Rasagiline is also an irreversible inhibitor of MAO-B and has similar clinical efficacy with selegiline.8 Furthermore, unlike selegiline, which is metabolized to 1-methamphetamine, rasagiline is not metabolized to an amphetamine derivative. Table 146.1 Summarizes the MAO-inhibitors currently available for use in the United States.

In addition to its antibiotic properties, linezolid, an oxazolidinone class antibiotic, is a reversible inhibitor of MAO, producing significant inhibition of MAO-A.

As a class, MAOIs are rapidly absorbed from the gastrointestinal tract and are bound extensively to plasma proteins. With overdose, the MAOIs initially stimulate release of neurotransmitters from the presynaptic neuron but later inhibit their release.

Clinical Features

Patients have MAOI toxicity as a result of an acute overdose or as a consequence of a food or drug interaction. Depending on the scenario that leads to toxicity, the clinical presentation may differ. Obtaining a thorough medication history is key to establishment of the diagnosis of MAOI toxicity. After overdose, an asymptomatic period followed by delayed toxicity can be a diagnostic clue. Patients may be asymptomatic for up to 24 hours before significant, possibly life-threatening toxicity develops. After this asymptomatic period, hyperadrenergic symptoms, including tachycardia, hypertension, and hyperthermia, can develop. Seizures, rhabdomyolysis, coma, and ultimately cardiovascular collapse can occur once presynaptic catecholamines are depleted.

Patients who take nonselective MAOIs in therapeutic doses are at risk for food-drug interactions. Tyramine is an indirectly acting sympathomimetic amine that is present in aged cheeses, red wine, smoked or pickled and aged meats, and other foods. Usually, tyramine is metabolized in the gut and liver by MAO, rarely causing systemic effects. When MAO-A is inhibited, tyramine is absorbed systemically and enters presynaptic vesicles, ultimately causing release of norepinephrine and serotonin into the synapse, leading to a hypertensive crisis.8 This tyramine syndrome, which can occur within minutes to hours of ingestion of foods with high tyramine content, is characterized by headache, hypertension, flushing, and diaphoresis. This syndrome can occur up to 3 weeks after discontinuation of a nonselective MAOI. Although it is theoretically possible, this syndrome is rare with therapeutic use of MAO-B inhibitors.8 A drug-drug interaction may result when MAOIs are combined with other agents that have serotonergic effects. A variety of prescription and over-the-counter medications may interact with MAOIs to produce a constellation of symptoms referred to as serotonin syndrome (see later section). This syndrome may be life threatening, so use of medications with serotonin-potentiating activity should be avoided in patients taking MAOIs.

Differential Diagnoses

The differential diagnosis for MAOI toxicity includes sympathomimetic drugs of abuse such as cocaine and amphetamine derivatives, anticholinergic (or antimuscarinic) toxicity (eg,
diphenhydramine, cyclic antidepressants, anti-Parkinson drugs, and jimson weed), and methylxanthine toxicity (eg, theophylline and caffeine). Other toxicological considerations include acute withdrawal states (eg, ethanol and benzodiazepines), neuroleptic malignant syndrome (NMS) and the serotonin syndrome from other serotonergic drug combinations. Non-toxicological causes to consider include environmental hyperthermia or heat stroke, febrile illness from infectious causes (eg, meningitis and encephalitis), pheochromocytoma, carcinoid syndrome, thyroid storm, and hypertensive emergency.

Diagnostic Testing

Laboratory abnormalities are nonspecific but can include hyperglycemia and leukocytosis, secondary to a hyperadrenergic state, and elevated creatine kinase due to rhabdomyolysis. Immunoadsay urine drug screens that are commonly used in the emergency department do not detect MAOIs, and even gas chromatography–mass spectroscopy of urine may fail to detect the presence of an MAOI. Patients taking selegiline will test positive for methamphetamine because methamphetamine is a metabolite.

Symptomatic patients presenting after an MAOI overdose should have an electrocardiogram (ECG) to assess the QT and QRS intervals. Patients with chest pain should be evaluated for myocardial infarction. Measurement of serum glucose and electrolytes are indicated if the patient is obtunded. Because of the potential for intracranial hemorrhage in the setting of severe MAOI-induced hypertension, patients with a seizure or focal neurological deficit should undergo a non–contrast-enhanced head computed tomography (CT) scan.

Management

As with most intoxication, supportive care is paramount. Central nervous system (CNS) excitation should be treated with intravenous (IV) administration of benzodiazepines such as lorazepam and diazepam in usual titrated doses. Hyperthermia should be treated with external cooling using evaporative techniques and strategic ice packing. Hyperthermia that persists, despite administration of benzodiazepines and external cooling measures, may need intubation, ventilation, and chemical paralysis with a non-depolarizing neuromuscular blocker. Because typically only a single dose of a paralytic is required, the authors recommend rocuronium during rapid sequence intubation. The use of succinylcholine may incite hyperkalemia if rhabdomyolysis has occurred, and fasciculation from succinylcholine might further increase metabolic heat production. Furthermore, many of these patients are acutely hyperkalemic, which is a relative contraindication to succinylcholine. Mild hypertension should not be treated, but sustained severe hypertension (eg, systolic blood pressure exceeding 200 mm Hg or a diastolic exceeding 100 mm Hg) is best managed with a rapid, short-acting agent such as phenolamine (titrated slowly by repeated IV doses of 1 mg every 3 minutes) or nitroprusside (0.25 to 0.5 mcg/kg/min by IV infusion). Treatment should target a 25% reduction in the mean arterial pressure. Hypotension should first be managed by volume resuscitation with normal saline. Persistent or severe hypotension requires treatment with infusion of a direct-acting catecholamine such as norepinephrine or epinephrine. Because hypotension and cardiovascular collapse after MAOI overdose are due to catecholamine depletion, the use of indirect-acting agents such as dopamine is not likely to be beneficial. Extracorporeal elimination is also unlikely to be beneficial because of extensive protein binding and large volume of distribution of MAOIs.

Patients presenting with a tyramine reaction may have spontaneous resolution of symptoms during 6 hours. Severe hypertension higher than 200 mm Hg systolic with symptoms such as headache, flushing, or chest pain should be treated with phenolamine or nitroprusside. Patients with persistent severe headache and hypertension should have a head CT scan to assess for intracranial hemorrhage. Patients with chest pain should be evaluated for myocardial infarction (see Chapter 68).

Treatment of suspected serotonin syndrome is supportive (see later section) and consists primarily of the administration of benzodiazepines.

Disposition

Patients presenting with an MAOI overdose should be admitted to a monitored setting for 24 hours due to the risk of delayed, rapid deterioration and development of hyperadrenergic symptoms. Asymptomatic patients chronically taking an MAOI who present out of concern for a possible drug–food interaction can be discharged after 6 hours if no signs of toxicity develop over that period of time.

TRICYCLIC ANTIDEPRESSANTS

Principles of Toxicity

In the 1950s, imipramine became the first TCA used for the treatment of depression. Until the introduction of the SSRIs, TCAs remained the primary agents for treatment of depression. The therapeutic benefit of TCAs results from monoamine reuptake inhibition. Whereas use of TCAs for treatment of depression has waned, use for other conditions, including treatment of migraines, various neuropathies, trigeminal neuralgia, and nocturnal enuresis has increased.

Clinical Features

Cyclic antidepressant toxicity can result from overdose of a TCA or drug interactions. Overdose is more commonly associated with life-threatening toxicity, but toxic effects can also occur when a TCA is combined with drugs that impair its metabolism through cytochrome P450. Tertiary amine TCAs such as amitriptyline, imipramine, and clomipramine are substrates of CYP2C19 and CYP1A2. Doxepin is also a substrate for CYP2D6. Drug-induced inhibition of these enzymes as well as genetic polymorphisms of these isoenzymes can decrease metabolism of these drugs, resulting in unexpectedly high serum concentrations and clinical toxicity. Conversely, inhibition of CYP2D6 and other P450 enzymes by these TCAs can also lead to increased serum concentrations of other drugs metabolized by the same enzymes. Because desipramine and nortriptyline are only weak CYP2D6 inhibitors, they cause fewer drug interactions. Another drug interaction that
occurs with TCAs is the serotonin syndrome, which can result when a TCA is combined with another serotonergic drug such as MAOI or SSRI.

After an overdose of a TCA, symptoms typically begin within 1 to 2 hours. With smaller ingested amounts, symptoms may be minimal and resolve quickly; patients who take large amounts may deteriorate rapidly soon after ingestion. Severely poisoned patients typically have symptoms within 6 hours of an overdose. Early cyclic antidepressant toxicity (within the first 2 hours) is primarily characterized by anticholinergic effects. These findings include dry mucosal membranes, urinary retention, and hot, dry skin. Despite having potent antimuscarinic properties, the pupils are often small due to alpha effects. Patients may be alert and confused, severely agitated, mute, hallucinating, or even deeply comatose. Speech is often rapid and mumbling in character. Seizures may occur and are likely to be multifactorial, resulting from increased synaptic monoamines, sodium channel inhibition, and gamma-aminobutyric acid (GABA) receptor antagonism. Early hypertension is common from the anticholinergic effects of the TCA and excess norepinephrine in the synapse from blockade of norepinephrine reuptake, but hypotension may also be due to alpha-receptor antagonism and also norepinephrine depletion. Later (2 to 6 hours post ingestion), myocardial depression resulting from severe sodium channel antagonism may also lead to hypotension and bradycardia.12 Significant sodium channel blockade is associated with widening of the QRS interval. The degree of widening is prognostic. A QRS wider than 100 msec is associated with seizures, where as a QRS complex wider than 160 msec is associated with ventricular dysrhythmias. TCAs also block potassium efflux, which leads to a prolonged QT interval.13 Significant sodium channel blockade is associated with wide QRS complexes, including the terminal 40 milliseconds of the QRS wave. Additional findings on the ECG include a rightward shift of the terminal 40 milliseconds of the QRS complex seen as an R wave in augmented vector right (aVR) longer than 3 milliseconds. Figure 146.1 demonstrates lead aVR following a tricyclic ingestion. QT prolongation is less important clinically than the QRS duration.

Urinary drug of abuse screens commonly test for the presence of TCAs, but a positive test result suggests only use of a TCA or another xenobiotic that cross-reacts with the screen (eg, antipsychotic medications, antimuscarinic agents, carbamazepine, or the muscle relaxant cyclobenzaprine). Quantitative serum tricyclic levels do not correlate with severity of illness.

Management

Ensuring stability of the airway, with adequate ventilation, and volume repletion are of primary importance. There are no randomized controlled trials demonstrating improved patient-oriented outcomes and decreased mortality with activated charcoal in patients with cyclic antidepressant overdose. Nonetheless, because of the high lethality of the acute overdose, a patient who presents within 1 hour after an overdose and who is awake, alert, and cooperative and is not exhibiting any signs of toxicity (eg, no tachycardia or intraventricular conduction delay) can be given activated charcoal. However, due to risk of seizures with subsequent aspiration, activated charcoal is not routinely recommended, other than in the specific setting described. There is no role for gastric lavage.

Patients with sinus tachycardia alone do not need specific treatment but should be monitored to detect QRS widening early in the clinical course. Early hypertension should not be treated. Hypotensive patients should first receive fluid resuscitation with an isotonic crystalloid. Patients who remain hypotensive should be treated with direct-acting vasoressors such as norepinephrine and epinephrine.

Hypertonic sodium bicarbonate is given only to treat specific evidence of sodium channel blockade such as a wide QRS and ventricular dysrhythmias. Sodium bicarbonate should not be given strictly due to tachycardia. Recommendations regarding the specific administration of sodium bicarbonate vary. We recommend a conservative approach by administering a bolus of 1 to 2 mEq/kg hypertonic sodium bicarbonate intravenous push (IVP) if the QRS interval exceeds 100 milliseconds. This dose may be repeated in a few minutes if the QRS does not narrow. After IV bolus, a sodium bicarbonate infusion can be used to maintain a pH between 7.50 and 7.55. Such an infusion can be created by the addition of 150 mEq sodium bicarbonate, 40 mEq potassium, and 850 mL of dextrose 5% in water (DSW). The infusion should be created with a 5% dextrose solution, and not normal saline, due to the risk of hypernatremia with the latter. The infusion should be administered at twice the normal maintenance rate, titrating to QRS width and pH. Alternatively, infusions of 1 mEq sodium bicarbonate per milliliter of fluid may be used if volume overload is a concern. Additional IV boluses of sodium bicarbonate may be

Differential Diagnoses

Many agents with anticholinergic properties produce similar clinical features as TCAs. Diphenhydramine and carbamazepine, in particular, can also produce seizure and sodium-channel blockade. Agents that produce sympathomimetic toxicity (eg, cocaine) or serotonin syndrome (eg, SSRIs, MAOIs) should be included in the differential diagnosis. Other drugs with sodium channel blockade, and hence a wide QRS complex, includes the Vaughan-Williams class IA antidysrhythmics (eg, procainamide, disopyramide, quinidine) and class IC antidysrhythmics (eg, flecainide, encainide, and propafenone), along with amantadine, carbamazepine, cocaine, diphenhydramine, mesoridazine, and thioridazine. Propoxyphene and propranolol can also cause an intraventricular conduction delay by sodium channel blockade but typically cause a bradycardic rhythm rather than a tachycardic rhythm.

The constellation of early anticholinergic symptoms, decreased level of consciousness followed by seizures, wide QRS, and cardiovascular collapse is highly suggestive of acute TCA overdose.

Diagnostic Testing

After overdose, the ECG can yield prognostic information. Early anticholinergic effects cause sinus tachycardia, which occurs vir-
toxicity and due to the potential for iatrogenic harm, its use is currently reserved for life-threatening toxicity that remains refractory to sodium bicarbonate administration. ILE should be administered only on advice of a medical toxicologist or regional poison center. If ILE is to be administered, there are several different dosing strategies. We recommend 1.5 mL/kg of a 20% lipid solution over 2 to 3 minutes. This bolus can be repeated once in 5 minutes if there is no clinical improvement. If clinical improvement does occur, the bolus may be followed by an infusion of 0.25 mL/kg/min for 15 to 30 minutes.

Despite recent enthusiasm for ILE, its use is not without associated complications, including extreme lipemia resulting in interference with laboratory blood tests (complete blood counts, chemistries, and coagulation studies), as well as acute pancreatitis, and acute respiratory distress syndrome.

Disposition
If the heart rate has not exceeded 100/minute for a period of at least 10 minutes, ECG intervals are normal, level of consciousness is normal, and no seizures have developed within 6 hours of a TCA overdose, it is unlikely that toxicity will occur. The patient can be medically cleared from the emergency department for psychiatric evaluation and disposition if needed. Patients with signs of cyclic antidepressant cardiotoxicity, seizures, or coma should be admitted to an intensive care unit.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS
Principles of Toxicity
In recent years, the SSRIs have become the mainstay for treatment of depression. As implied by their name, these drugs prevent the presynaptic reuptake of serotonin without affecting the synaptic concentration of other monoamines. Some of the more commonly used SSRIs available today include escitalopram and
its enantiomer citalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline.

SSRIs have a wide therapeutic index. Most SSRIs undergo hepatic metabolism. There is considerable variability in their half-life; however, paroxetine has one of the shortest half-lives (17 hours) compared with fluoxetine, which has one of the longest half-lives (53 hours for parent drug, 240 hours for active metabolite).

Clinical Features

Overdose of SSRIs is usually well tolerated and rarely fatal, with ingestions of up to 30 times the daily dose associated with few or no symptoms. Gastrointestinal upset and mild CNS depression can occur with large overdoses. Coma and seizures are rare, with incidences of approximately 2% for each. The incidence of serotonin syndrome after SSRI overdose is variable, up to 15%, but most other series report a much lower incidence.

Citalopram overdose deserves special mention because of a higher rate of QTc prolongation and seizures compared with other SSRIs.21-22 There has been some suggestion that the QT prolongation may be delayed with citalopram ingestion. However, there is not convincing data to support this delayed onset of toxicity. The QT prolongation does, however, appear to be dose dependent.23 Despite being the active enantiomer of citalopram, escitalopram appears to be less toxic than citalopram, with a lower incidence of seizure and QTc prolongation.21

The therapeutic administration of SSRIs may be associated with the syndrome of inappropriate antidiuretic hormone secretion (SIADH).24 Most cases of hyponatremia develop shortly after commencing care. The overall incidence is not well documented. However, in one small study, 12.5% of elderly patients taking an SSRI had SIADH, with an additional 12.5% of patients having mild asymptomatic hyponatremia.

Differential Diagnoses

The differential diagnosis for SSRI toxicity includes cyclic antidepressants, MAOIs, sedative hypnotics (eg, benzodiazepines, barbiturates), SNRIs, neuroleptic agents, and atypical antipsychotics.

Diagnostic Testing

Diagnosis of SSRI toxicity is often dependent on obtaining a history of overdose. Clinical features of toxicity are similar to those seen after overdose of many other toxicants. An ECG can assess for conduction disturbances, especially QT prolongation. Specific SSRI levels are not performed by most hospital laboratories and do not influence management, although they may help confirm overdose retrospectively. A standard urine drug of abuse screen will not detect an SSRI.

Management

Treatment of an SSRI overdose is largely supportive. There is no role for activated charcoal or gastric lavage. Only rarely will patients require tracheal intubation because of loss of airway reflexes. For patients with a corrected QT interval greater than 500 msec, 2 grams of IV magnesium sulfate should be administered. IV administration of benzodiazepines (0.05 to 0.1 mg/kg of lorazepam via rapid IV bolus; or 0.1 to 0.2 mg/kg diazepam via rapid IV bolus) should be used to treat agitation and seizures.

Disposition

Patients who overdose with an SSRI who are asymptomatic after 6 hours of monitoring are unlikely to have toxicity. Some authors advocate for 12 hours of observation after the ingestion of more than 1000 mg of citalopram or escitalopram, although that recommendation is not universally accepted. If a patient with citalopram ingestion is to be cleared after 6 hours, a repeat ECG should be performed to assess the QT interval. Symptomatic patients should be admitted to a monitored care setting. Those patients with an intent of self-harm should be evaluated by a psychiatric service.

SEROTONIN-NOREPINEPHRINE REUPTAKE INHIBITORS AND NOREPINEPHRINE REUPTAKE INHIBITORS

Principles of Toxicity

Duloxetine, venlafaxine, desvenlafaxine, milnacipran, and levomilnacipran are collectively referred to as serotonin-norepinephrine reuptake inhibitors (SNRIs). All of these agents, except milnacipran, are approved for use in the United States for treatment of major depression. Milnacipran, despite being used as an antidepressant in Europe, is only approved for treatment of fibromyalgia in the United States. Some of these agents are also approved for other disorders. For example, venlafaxine can be used to treat panic disorder, generalized anxiety disorder, or social phobia, whereas duloxetine is also used to treat chronic musculoskeletal pain, diabetic neuropathy, fibromyalgia, and generalized anxiety disorder. Venlafaxine and its active metabolite desvenlafaxine are both available medicinally. The SNRIs may also produce dose-dependent inhibition of sodium channels. Reboxetine is an isolated norepinephrine reuptake inhibitor. It is also used for the treatment of depression.

Clinical Features

Unlike the SSRIs, which are relatively benign in overdose, ingestion of any of the SNRIs can be dangerous. Fatal ingestions have been described with virtually all of the SNRIs. All of these agents may produce hyperadrenergic symptoms, including tachycardia and hypertension. Rarely, hypotension can be observed after massive overdose.25-26 It is hypothesized that the hypotension may be the result of an acute cardiomyopathy.27-28 Seizures can occur following ingestion of the SNRIs.29-30 Unlike bupropion, however, which can have delayed onset of seizures, the onset of seizures following an SNRI ingestion would be expected to occur within the first several hours post ingestion. Rhabdomyolysis has been reported independent of seizure activity following ingestions of venlafaxine.31 Venlafaxine and desvenlafaxine overdoses can result in cardiovascular toxicity, manifesting as intraventricular conduction delay and ventricular dysrhythmias.32 Venlafaxine has also been associated with QT prolongation.33 Lastly, based on their mechanism of action, serotonin syndrome may develop after ingestion of these agents.

Differential Diagnoses

The differential diagnosis for SNRIs toxicity includes cyclic antidepressants, MAOIs, sedative hypnotics, serotonin reuptake inhibitors, neuroleptic agents, and atypical antipsychotic medications.

Diagnostic Testing

Specific drug levels are not rapidly available and do not aid management. An ECG can detect QRS or QT interval prolongation. SNRIs are not detected by urine drug of abuse screens, but venlafaxine is associated with a false-positive phencyclidine screen.34 In cases of a venlafaxine ingestion, a creatinine kinase and renal function tests should be obtained to assess for acute
rhabdomyolysis. As with any multidrug ingestion, serum acetaminophen and salicylate levels should be measured.

Management

Care of the patient with an SNRI overdose is supportive, with focus on ensuring airway patency and adequate ventilation. There is no role for activated charcoal or gastric emptying. Hypotension (systolic blood pressure <90 mm Hg) should first be treated with a 20 cc/kg bolus of 0.9% normal saline. This bolus can be repeated if necessary. If hypotension still persists, a direct-acting vasopressor (such as epinephrine or norepinephrine) should be used. Intraventricular conduction delay with a widened QRS on ECG should be treated with sodium bicarbonate infusions (as described in the Tricyclic Antidepressants section earlier). First-line treatment of seizures is the IV administration of a benzodiazepine such as lorazepam or diazepam.

Disposition

Patients who are asymptomatic with a normal 12-lead ECG after an observation period of 6 hours can be cleared for discharge after appropriate psychiatric consultation. Patients with an intentional ingestion who develop manifestations of neurologic or cardiovascular toxicity (such as sedation, hypotension, tachycardia, and so on) should be observed in an in-patient monitored setting. Those with profound CNS depression or hemodynamic instability warrant intensive care unit admission. Symptomatic patients should be admitted to a monitored care setting. Those patients with conduction delay and coma should be admitted to an intensive care unit.

MISCELLANEOUS ANTIDEPRESSANTS

Bupropion

Bupropion is a unique class of antidepressant, which is also used for smoking cessation.36 The primary mechanism of action is inhibition of dopamine and norepinephrine reuptake, but it can also act as a noncompetitive inhibitor of nicotinic acetylcholine receptors.37 Seizure activity is a dose-dependent phenomenon and can occur with therapeutic dosing or overdose of bupropion.38 Seizures are relatively common after overdose and occur in approximately 30% of cases, the majority of which are initially tachycardic.38-39 Sinus tachycardia, tonic-clonic seizures, and agitation are common after overdose. Unlike many agents that produce seizures acutely following overdose, ingestion of extended release bupropion can produce delayed onset seizures. Both QRS and QT prolongation can occur with toxicity. Treatment is primarily supportive. Activated charcoal or gastric emptying are not indicated. Patients with large overdoses may require endotracheal intubation because of CNS and respiratory depression. Lorazepam or diazepam is effective for terminating seizures. If seizures persist, phenobarbital or other GABA agonists may be used. Sodium bicarbonate (150 mEq IV or 3 mEq/kg for pediatric patients) should be administered for any QRS prolongation. Additional bicarbonate should be given based on subsequent ECGs. Resuscitative ILE therapy has been described in anecdotal case reports with severely poisoned patients refractory to standard management measures. ILE should be undertaken only on the advice of a medical toxicologist or regional poison center.

Trazodone

Trazodone is an atypical antidepressant with a mechanism of action that includes antagonism of the 5-hydroxytryptamine type 2A (5-HT2A) receptor and alpha1 receptor. In addition, it is a serotonin receptor antagonist and reuptake inhibitor. Its use as an antidepressant has been historically somewhat limited by adverse effects (such as orthostatic hypotension, priapism, and sedation), although once-daily formulation has recently been released.40 Priapism is probably a result of trazodone’s alpha-antagonism, with an incidence of 1/100 to 1/10,000. Whereas many drugs are associated with priapism, particularly those with alpha-antagonism or inhibition of type 5 phosphodiesterase, trazodone is responsible for a disproportionate number of reported cases.

After overdose, sedation and hypotension due to vasodilation are expected. Priapism is not typically associated with overdose of trazodone. Prolongation of the QT interval may occur. Management is supportive, with airway protection, IV fluid resuscitation, and use of alpha-adrenergic agonists such as norepinephrine as needed for refractory hypotension. Activated charcoal and gastric emptying are not indicated.

Nefazodone

Nefazodone, a phenylpiperazine antidepressant, is structurally similar to trazodone. It acts as an antagonist at the 5-HT1A receptor, and chronic administration is associated with receptor downregulation. Nefazodone is associated with weak inhibition of norepinephrine and serotonin reuptake. It is metabolized to several active metabolites. After overdose, most patients remain asymptomatic. Antagonism of the alpha1 receptor is responsible for the orthostatic hypotension that can occur. Treatment is primarily supportive.

SEROTONIN SYNDROME

Principles of Toxicity

Serotonin syndrome is a potentially lethal condition resulting from excess serotonin accumulation in the synaptic cleft. This syndrome occurs after an isolated overdose of an SSRI, but it is more commonly a result of drug interactions, especially with drug combinations that raise synaptic serotonin concentrations by different mechanisms. Agonism of the 5-HT1A receptor appears to be largely responsible for this condition in humans.41 Whereas numerous xenobiotics have been implicated in causing serotonin syndrome, some of the most common are the SSRIs, SNRIs, TCAs, MAOIs, dextromethorphan, amphetamines, and designer amphetamines, including methylenedioxymethamphetamine (“ecstasy”), cocaine, meperidine, lithium, tramadol, buspirone, lisuride, lysergic acid diethylamide (LSD), and linezolid (Box 146.1). Serotonin syndrome is more likely to develop when drugs from different classes are combined, resulting in increased serotonin in the synaptic cleft from different mechanisms (eg, increased release and impaired uptake).

Clinical Features

Serotonin syndrome is described as a triad of mental status changes, autonomic instability, and increased neuromuscular activity, but the condition exists along a spectrum; some patients have only mild tremor and diarrhea, whereas others exhibit life-threatening manifestations. Clinical features may include tremor, akathisia, gastrointestinal illness, clonus (inducible or spontaneous), rigidity, fever, seizures, and autonomic instability. The clonus is typically more pronounced in the lower extremities than in the upper extremities. After an acute overdose of a serotonergic agent, symptom onset typically begins within several hours. With proper treatment, symptoms usually resolve within 24 hours but can persist for several days in severe cases.
BOX 146.1

Xenobiotics Commonly Implicated in Serotonin Syndrome

Analgesics: Tramadol, meperidine, pentazocine
Drugs of abuse: Cocaine, amphetamine derivatives (eg, methylenedioxymethamphetamine), lysergic acid diethylamide (LSD)
Monoamine oxidase inhibitors (MAOIs) (eg, isocarboxazid, linezolid, phenelzine, moclobemide, selegiline)
Miscellaneous: Dextromethorphan, lithium, metoclopramide, St. John’s wort
Selective serotonin reuptake inhibitors (SSRIs) (eg, milnacipran, venlafaxine)
Serotonin-norepinephrine reuptake inhibitors (SNRIs) (eg, citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline)
Tricyclic antidepressants (TCAs) (eg, amitriptyline, clomipramine, desipramine, doxepin, imipramine, nortriptyline)

BOX 146.2

The Hunter Criteria for Serotonin Syndrome

In the setting of exposure to a known serotonergic agent, serotonin syndrome can be diagnosed by the presence of any of the following:
- Spontaneous clonus
- Inducible clonus and agitation or diaphoresis
- Ocular clonus and agitation or diaphoresis
- Tremor and hyperreflexia
- Hypertonic with temperature >38°C and ocular clonus or inducible clonus

Differential Diagnoses

The differential diagnosis of serotonin syndrome includes NMS, malignant hyperthermia, sympathomimetic toxicity, anticholinergic toxicity, strychnine toxicity, bupropion toxicity, and GABA withdrawal. Non-toxicologic considerations include thyroid storm, meningitis, idiopathic seizure, intracranial hemorrhage, and hypoglycemia.

Diagnostic Testing

There is no “gold standard” for the diagnosis of serotonin syndrome. Laboratory studies cannot be used to confirm or to exclude the diagnosis of serotonin syndrome. Rhabdomyolysis and hyperkalemia can occur as a result of increased neuromuscular activity, and these should be screened for as indicated on the basis of the clinical examination.

The Sternbach criteria were developed in the 1990s and became the first widely used diagnostic algorithm. Additional criteria, including the Hunter criteria and the Boyer and Shannon criteria, have been developed. The Hunter criteria (Box 146.2) appear to be more sensitive than the Sternbach criteria, with fewer false positives.

In general, a history of overdose or of recently starting an additional serotonergic agent along with clinical findings consistent with this diagnosis should raise the concern for serotonin syndrome.

Management

Management is supportive, with removal of the offending agents being paramount. Mild cases may require only discontinuation of the offending agent and low-dose benzodiazepines (eg, 5 to 10 mg of IV diazepam) for rigidity. More severe cases may require IV fluid resuscitation and large doses (eg, 10 to 20 mg of IV diazepam, with titration in 10 mg aliquots) of benzodiazepines or other sedative-hypnotic agents to gain control of symptoms. Cyproheptadine, a 5-HT2A antagonist, is an adjunctive therapy for more severe cases, but there are no randomized controlled trials demonstrating improved benefit with cyproheptadine over supportive care and benzodiazepines alone. If cyproheptadine is available, the syndrome is severe or refractory to treatment, and the clinician is confident with the diagnosis, we recommend a single dose of 12 mg of cyproheptadine for patients with serotonin syndrome. If anticholinergic toxicity remains on the differential diagnosis, cyproheptadine should not be given, because it can worsen anticholinergic toxicity. Patients with hyperthermia that does not respond promptly to sedation with benzodiazepines should receive a nondepolarizing neuromuscular blocking agent (eg, rocuronium) during rapid sequence intubation. Typically only a single dose of a long-acting neuromuscular blocking agent is required.

Disposition

Patients with all but the mildest forms of serotonin syndrome should be admitted to a monitored care setting. Those with unresponsiveness and rigidity should be admitted to an intensive care unit.

DISCONTINUATION SYNDROMES

After the abrupt discontinuation of certain antidepressants, patients can experience a withdrawal, or discontinuation, syndrome. Unlike potentially life-threatening GABA withdrawal from ethanol or benzodiazepines, the discontinuation syndrome from antidepressants is rarely life threatening but can result in significant discomfort. One notable exception involves neonates born to mothers using TCAs who can have serious, potentially life-threatening withdrawal. Antidepressant discontinuation syndrome does not always develop, but when it does, it typically starts within the first 3 days after therapy is stopped. This syndrome is difficult to distinguish from recurrence of the underlying depression, which overlaps with some symptoms.

Antidepressant discontinuation syndrome occurs with all major classes of antidepressants. Withdrawal from SSRIs involves both physical and psychological symptoms, most commonly nausea, lethargy, headache, and dizziness. The symptoms can be divided into six general categories: dysequilibrium (eg, dizziness, ataxia), sleep disturbances, gastrointestinal symptoms, affective symptoms (eg, irritability, anxiety), sensory symptoms (eg, electric shock–like sensation, paresthesias), and general somatic symptoms (eg, headache, tremor, anorexia, diaphoresis). The syndrome is more common after discontinuation of drugs with shorter half-lives (eg, paroxetine) than of drugs with longer half-lives (eg, fluoxetine). TCA withdrawal is similar to SSRI withdrawal, although sensory abnormalities and equilibrium disturbances are rare with TCA discontinuation. Non–life-threatening arrhythmias are rare after discontinuation of the TCAs.

Patients with mild withdrawal symptoms do not require any specific therapy. For those patients with more severe symptoms, treatment involves restarting of the antidepressant, followed by a gradual tapering dose.

146.5. A 57-year-old woman presents with altered mental status. A friend states that the patient takes antidepressant medications and has recently been complaining of symptoms of an upper respiratory tract infection. The patient is noted to have a temperature of 39.2°C and a pulse of 135 beats/minute. Otherwise, her vital signs are within normal limits. On examination, she has a tremor, myoclonus, and diaphoresis. Which of the following is the most consistent with this presentation?

A. Anticholinergic syndrome
B. Cocaine intoxication
C. Cyclic antidepressant overdose
D. Neuroleptic malignant syndrome (NMS)
E. Serotonin syndrome

Answer: E. Symptoms of serotonin syndrome include altered mental status, agitation, ataxia, diaphoresis, diarrhea, hyperreflexia, hyperthermia, myoclonus, shivering, and tremor. Many of the symptoms are similar to symptoms caused by NMS and sympathomimetic overdoses; however, myoclonus is unique to the serotonin syndrome. Additional historical features consistent with the serotonin syndrome are the fact that the patient is taking an antidepressant, possibly a selective serotonin reuptake inhibitor (SSRI), and has likely added an over-the-counter "cold" medication. Many of these medications contain dextromethorphan, which also decreases serotonin reuptake and can precipitate the serotonin syndrome in patients taking SSRIs.

146.6. A 24-year-old man presents after taking an overdose of his antidepressant. He does not know the name of the drug. He has no complaints, and his vital signs and physical examination findings are normal. Soon after completing your evaluation, the patient experiences a tonic-clonic seizure. Which of the following antidepressants is most likely to produce seizures without other symptoms of severe toxicity?

A. Amitriptyline
B. Bupropion
C. Fluoxetine
D. Phenerazine
E. Trazodone

Answer: B. Bupropion can induce seizures even at therapeutic levels. Other adverse effects include tachycardia, tremulousness, hallucinations, and QRS prolongation. Cyclic antidepressants (amitriptyline), selective serotonin reuptake inhibitors (SSRIs; fluoxetine), and monoamine oxidase inhibitors (MAOIs; phenerazine) can also cause seizures but less frequently than bupropion and usually with other symptoms of serious intoxication such as central nervous system (CNS) depression or QRS prolongation.

146.7. A patient is prescribed a new medication that he takes each night. After 4 days, he is drowsy and noted to have orthostatic hypotension, nausea, vomiting, and priapism. What medication is most likely involved?

A. Amitriptyline
B. Bupropion
C. Fluoxetine
D. Phenerazine
E. Trazodone

Answer: E. Trazodone and nefazodone may cause orthostatic hypotension and lethargy. Priapism is a relatively unique complication of trazodone and is more common with therapeutic use rather than in acute overdose.

146.8. A patient presents after a substantial accidental overdose of her monoamine oxidase inhibitor (MAOI), which she confused with her megavitamin therapy. There is no need for psychiatric evaluation. She is asymptomatic and has normal vital signs and a normal physical examination. What is the appropriate disposition?

A. Admit to intensive care unit for a minimum of 24 hours of observation
B. Admit to ward for a minimum of 24 hours of observation
C. Discharge home
D. Observe for 6 hours, then discharge home
E. Observe for 12 hours, then discharge home

Answer: A. All patients who overdose on MAOIs should be admitted for at least 24 hours of observation because symptom onset is often delayed. In addition, the effects of overdose may be severe and require aggressive therapy.
Cardiovascular drugs are a common cause of poisoning in the United States; in 2013, 101,544 exposures to cardiovascular drugs were reported to United States poison control centers.1 Cardiovascular drugs are the seventh most common cause of poisoning and the second most common cause of poisoning death in the United States, accounting for more than 10% of all poisoning fatalities. Of the plethora of cardiovascular drugs, three classes—cardioactive steroids (primarily digoxin), beta-adrenergic blockers, and calcium channel blockers—account for the majority of fatalities. Because the commonality between all three of these drug classes is a combination of bradycardia and hypotension, it is critical for emergency clinicians to be familiar with clonidine and endogenous or administered to treat bradydysrhythmias or hypertension, play an important role in digoxin toxicity. Because bradydysrhythmias and tachydysrhythmias can appear and alternate in the same patient, administration of drugs to treat tachycardias may later contribute to more refractory bradycardias and AV block.

Digoxin also exerts three primary effects on Purkinje fibers: (1) decreased resting potential, resulting in slowed phase 0 depolarization and conduction velocity; (2) decreased action potential duration, which increases sensitivity of muscle fibers to electrical stimuli; and (3) enhanced automaticity resulting from increased rate of phase 4 repolarization and delayed after-depolarizations. These mechanisms account for an increase in premature ventricular contractions, which is the most common electrocardiographic manifestation of digoxin toxicity. At extremes of toxicity, these effects result in a dangerous sensitivity to mechanical and electrical stimulation. Interventions with pacemaker wires, catheters, and cardioversion can result in asystole, ventricular tachycardia, and ventricular fibrillation.

Unlike most cardiovascular drugs, digoxin can produce virtually any dysrhythmia or conduction block, and bradycardias are as common as tachycardias (Box 147.1). However, none is unique to digoxin, and because they can all occur in the setting of ischemic and other heart disease, digoxin toxicity remains a clinical rather than an electrocardiographic diagnosis.

The volume of distribution (Vd) of digoxin is 5 L/kg for adults but varies from 3.5 L/kg in premature infants to 16.3 L/kg in older infants. This indicates that only a small fraction of digoxin remains in the intravascular space, and the drug is highly concentrated in cardiac tissue. The myocardial-to-serum ratio at equilibrium ranges from 15:1 to 30:1. In contrast, the Vd for digitoxin is only 0.5 L/kg, giving it a different pharmacokinetic profile.

The elimination half-life of digoxin, which is primarily excreted in the urine, is 36 hours, and the half-life of digitoxin, which is metabolized in the liver, is 7 days. Whereas digoxin undergoes a small enterohepatic circulation, the circulation for digitoxin is large.

Protein binding varies from 20% to 30% for digoxin to 95% for digitoxin. The significant protein binding and large volumes of distribution of digoxin suggest that hemodialysis, hemoperfusion, and exchange transfusion are ineffective. The long half-lives have therapeutic implications for temporizing measures such as pacemakers, atropine, and antidysrhythmic drugs compared to the more definitive treatment of Fab fragments.

Multiple drugs and disease states can negatively alter absorption, Vd, protein binding, and elimination, rendering the heart.
more susceptible to digoxin toxicity. The factors listed in Box 147.2 are especially important risk factors in chronic intoxication.

Clinical Features

The symptoms and signs of chronic digoxin toxicity are nonspecific. The most common symptoms, in more than 80% of cases, are nausea, anorexia, and fatigue; but a variety of gastrointestinal, neurologic, and ophthalmic disturbances also occur (Box 147.3). Visual disturbances include decreased visual acuity, scotomata, photophobia, and chromatopsia (aberrations of color vision). Digoxin intoxication should be considered in any patient receiving maintenance therapy who has consistent symptoms, no matter how vague, particularly if presenting with new conduction disturbances or dysrhythmias.

There are significant differences between acute and chronic toxicity (Table 147.1). Chronic poisoning has an insidious onset

**BOX 147.2**

Factors Associated With Increased Risk of Digoxin Toxicity

Renal insufficiency
Heart disease
Congenital heart disease
Ischemic heart disease
Congestive heart failure
Myocarditis
Electrolyte imbalance
Hypokalemia or hyperkalemia
Hypomagnesemia
Hypercalcemia
Alkalosis
Hypothyroidism
Sympathomimetic drugs
Cardiotoxic co-ingestants
Beta-blockers
Calcium channel blockers
Tricyclic antidepressants
Drug interactions
Quinidine, amiodarone
Erythromycin
Verapamil, diltiazem, nifedipine
Captopril
Elderly woman

Visual and auditory hallucinations
Paranoid ideation, acute psychosis
Somnolence
Abnormal dreams
Paresthesias and neuralgia
Aphasia
Seizures

**BOX 147.1**

Dysrhythmias Associated With Digoxin Toxicity

**NONSPECIFIC**
PVCs, especially bigeminal and multiform
First-, second-, (Wenckebach’s), and third-degree AV block
Sinus bradycardia
Sinus tachycardia
SA block or arrest
Atrial fibrillation with slow ventricular response
Atrial tachycardia
Junctional (escape) rhythm
AV dissociation
Ventricular bigeminy and trigeminy
Ventricular tachycardia
Torsades de pointes
Ventricular fibrillation

**MORE SPECIFIC BUT NOT PATHOGENIC**
Atrial fibrillation with slow, regular ventricular rate (AV dissociation)
Nonparoxysmal junctional tachycardia (rate 70 to 130 beats/min)
Atrial tachycardia with block (atrial rate usually 150 to 200 beats/min)
Bidirectional ventricular tachycardia

AV, Atrioventricular; PVCs, premature ventricular contractions; SA, sinoatrial.
biotic found in common Monkshood (Aconitum napellus), may also mimic digoxin poisoning. Central nervous system (CNS) depression or confusion may be due to various depressant drugs (opioids, major tranquilizers, sedative hypnotic agents) and toxins, as well as infection, trauma, inflammation, and metabolic derangements. Visual disturbances caused by digoxin are binocular and are often not reported by the patient; unfortunately, they are not specific to digoxin poisoning. Methanol, metformin, ethambutol, ethyl chloride, quinine, and other antimalarial medications are all capable of producing visual disturbances. Gastrointestinal disturbances are common and nonspecific and may be misdiagnosed as gastritis, enteritis, or colitis.

**Diagnostic Testing**

Diagnosis and management rely heavily on serum digoxin concentrations, but it is the steady state, rather than peak concentration, that correlates with tissue toxicity and is used to calculate antidote dosages. Peak concentrations after an oral dose of digoxin occur in 1.5 to 2 hours, with a range of 0.5 to 6 hours. Steady-state serum concentrations are not achieved until after alpha distribution, or 6 to 8 hours after a dose or overdose, and may be only one fourth to one fifth of the peak concentration. The ideal serum digoxin concentration for patients with heart failure is considered to be 0.7 to 1.1 ng/mL, although laboratory “normals” are often reported up to 2.0 ng/mL. Serum steady-state digoxin concentrations of 1.1 to 3.0 ng/mL are difficult to interpret; that is, concentrations as low as 1.1 ng/mL have been associated with toxicity, and patients with levels up to 3.0 ng/mL can be asymptomatic. The incidence of digoxin-incited dysrhythmia reaches 10% at a concentration of 1.7 ng/mL and rises to 50% at a concentration of 2.5 ng/mL. Determination of a serum digoxin concentration measured too soon after the last maintenance dose falsely suggests toxicity, especially in cases of chronic intoxication, in which significant morbidity and mortality can occur at levels of 2 to 6 ng/mL. After an acute massive overdose in a patient who is rapidly becoming symptomatic, however, it may be impractical to wait 6 to 8 hours for the first measurement. It is unlikely that early

and is accompanied by a higher mortality rate that is probably due in part to underlying heart disease and chronic accumulation of the toxin. In cases of chronic intoxication, the level with a 50% mortality (LL50) is only 6 ng/mL. The LL50 for acute intoxication is not known, but it is much higher, especially in children. Although toxicity increases with greater body load, there is no clear correlation with amount ingested, especially in children, and many patients with large acute ingestions or high serum levels become only mildly symptomatic. The association of hyperkalemia with acute toxicity is obvious given the mechanism of digoxin; either hypokalemia or hyperkalemia may occur with chronic toxicity.

**Differential Diagnoses**

No sign or symptom, including dysrhythmia, is unique to digoxin poisoning, so the differential diagnosis is broad. Intrinsic cardiac disease as well as other cardiotoxic drugs should be considered. Cardioactive steroid poisoning from plants is rare, but presents similarly to digoxin toxicity. Common examples include oleander (Nerium oleander; Fig. 147.2) and lily-of-the-valley (Convallaria majalis; Fig. 147.3). Aconitine, a sodium-channel opening xeno-
concentrations exceeding 10 to 20 ng/mL will fade to clinical insignificance at 6 to 8 hours after ingestion.

Management

Fab Fragments (Digifab)

The treatment of significant digoxin poisoning is the administration of digoxin-specific fragment antigen-binding (Fab) antibodies (Digifab); all other interventions are considered complementary.

The mortality rate of digoxin poisoning before Fab fragment therapy was 23% despite all of the interventions described. Fab fragment treatment is well established in both chronic and acute poisonings, with a response rate approaching 90%. Non-responders usually receive Fab fragments too late, have concomitant poisoning, or are compromised by underlying disease.

Digoxin antibodies are derived from sheep. Allergic reactions only occur in less than 1% of cases but are slightly more common in patients with asthma. Reactions have included erythema, urticaria, and facial edema, all of which are responsive to the usual treatment for allergic reactions. Other expected reactions when Fab fragments neutralize digitalis include hypokalemia, exacerbation of congestive heart failure, and increase in ventricular rate with atrial fibrillation all of which occur infrequently. Two Fab fragment preparations were previously available; however, Digibind has been discontinued, leaving Digifab as the only available product in the United States. If vials of Digibind are still available at a given institution, they require a 0.22-µm membrane filter for proper use; such a filter is not required for Digifab.

Fab fragment treatment is best reserved for cases of serious cardiovascular toxicity rather than for routine or prophylactic administration with higher than expected serum concentrations. In acute poisoning, Fab fragments should be used for a serum potassium level above 5.0 mEq/L or unstable dysrhythmias such as symptomatic sinus bradycardia, ventricular dysrhythmias, or second- or third-degree heart block unresponsive to atropine. Fab fragment therapy should be used before transvenous pacing, because the latter is believed to carry risk of ventricular dysrhythmia, although the evidence for this is mixed.

The median time to initial response is 15 minutes after completion of the Fab infusion, but complete resolution of digitalis toxic rhythms may require hours. Late administration of Fab fragments has resuscitated 54% of patients who have suffered cardiac arrest. Fab fragments should be administered whenever hemodynamic compromise occurs in the setting of a digoxin-induced toxic dysrhythmia or heart block; a full list of indications is included in Box 147.4.

Dosing of Fab fragments is based upon the patient’s clinical status. If the patient is in cardiac arrest, the maximum number of vials of Fab fragments available (up to 10) should be administered undiluted as an intravenous (IV) bolus. If the patient is hemodynamically unstable, there is no time to assess serum digoxin concentration, and the ingested amount is also unknown, in acute toxicity 10 vials (if available) should be administered over 30 minutes, and three to six vials should be administered in chronic poisoning. In a hemodynamically unstable patient after an acute digoxin ingestion where the serum digoxin concentration is unknown but the amount of digoxin ingested is known, we recommend full reversal based upon the following concept: one vial of Digifab contains 40 mg of Fab fragments, which bind 0.5 mg of digoxin or digitoxin (Box 147.5). If, in acute or chronic toxicity, the patient is hemodynamically unstable and the steady-state serum digoxin concentration is known, we recommend full reversal with Fab fragments based upon the digoxin concentration utilizing the formula in Boxes 147.6 and 147.7.

In hemodynamically stable patients, we recommend a more conservative dosing regimen of Fab fragments. The total body

**BOX 147.4**

**Recommendations for Administration of Digoxin Antibody Fragments**

**ADULTS**

1. Ventricular dysrhythmias more severe than premature ventricular contractions
2. Progressive and hemodynamically significant bradydysrhythmias unresponsive to atropine
3. Serum potassium concentration above 5.0 mEq/L
4. Rapidly progressive rhythm disturbances or rising serum potassium level
5. Co-ingestion of cardiotoxic drugs such as beta-blockers, calcium channel blockers, or tricyclic antidepressants with concomitant shock
6. Ingestion of plant known to contain cardioactive steroids plus severe dysrhythmias
7. Acute ingestion of more than 10 mg plus any one of factors 1 through 6 above
8. Steady-state serum digoxin concentration above 6 ng/mL plus any one of factors 1 through 6 above

**CHILDREN**

1. Ingestion of more than 0.1 to 0.3 mg/kg or steady-state digoxin concentration above 5 ng/mL plus rapidly progressive symptoms or signs of cardioactive steroid intoxication or potentially life-threatening dysrhythmias or conduction blocks or serum potassium concentration above 6 mmol/L
2. Co-ingestion of other cardiotoxic drugs with additive or synergistic toxicity
3. Ingestion of plant known to contain cardioactive steroids plus severe dysrhythmias

**BOX 147.5**

**Sample Calculation of DigiFab Based on Ingested Dose of Digoxin or Digitoxin**

Case: A toxic-appearing 40-year-old woman has ingested fifty 0.25-mg digoxin tablets.

\[
\text{Body load} = \text{amount ingested} \times 0.8 \text{ (bioavailability of digoxin tablets)} = 12.5 \text{ mg} \times 0.8 = 10 \text{ mg}
\]

Dose of digoxin Fab fragments (in vials) = 10 mg + 0.5 mg bound per vial = 20 vials

*Formula from GlaxoSmithKline, 2008.

**BOX 147.6**

**Sample Calculation of DigiFab Based on Steady-State Digoxin Concentration**

Case: A toxic-appearing 4-year-old child weighing 20 kg has a digoxin level of 16 ng/mL 8 hours after ingestion of an unknown number of digoxin tablets.

\[
\text{Dose (in number of vials)} = (\text{serum digoxin concentration} \times \text{weight in kg}) + 100 = (16 \times 20) + 100 = \text{approximately 3 vials}
\]

*Formula from GlaxoSmithKline 2008; assumes \(V_d = 5 \text{ L/kg.} \)
burden of digoxin is often overestimated. Furthermore, the incidence of life-threatening dysrhythmias, even in reported large ingestions, is low, suggesting most patients do not require Fab fragments. Pharmacokinetic modeling of digoxin toxicity suggests smaller doses of Fab fragments are adequate to reverse toxicity. Therefore, in acute digoxin poisoning, we recommend two vials, repeated as needed using clinical markers of toxicity such as evidence of shock or severe dysrhythmias. For chronic poisoning, we recommend one vial with a repeat dose at 60 minutes if the patient is still symptomatic. Repeat dosing sooner is reasonable if the patient becomes unstable.

Because most assays measure both bound and unbound drug, digoxin concentrations will be elevated for up to 1 week after Fab fragments administration, with values often greater than 100 ng/mL once Fab fragments have been administered. Measurement of free serum digoxin is possible in some institutions, but it is more meaningful to follow the patient clinically.

Electrolyte Correction

In cases of chronic toxicity, which may be exacerbated by hypokalemia, maintenance of the serum potassium level to at least 3.5 to 4 mEq/L is an important early treatment. Potassium can be administered orally (which is safer) or intravenously at a rate of less than 40 mEq/hr.

In acute poisoning, serum potassium concentration may begin to rise rapidly within 1 to 2 hours of ingestion. Potassium should be withheld, even if mild hypokalemia is measured initially. The initial serum potassium concentration may in fact be a better predictor of mortality than the initial digoxin concentration. Before Fab treatment was available, up to 50% of the patients with serum potassium concentrations between 5.0 and 5.5 mmol/L died. In the setting of digoxin toxicity, we recommend initiating Fab treatment based solely on, a serum potassium concentration greater than 5 mmol/L.

The decision to administer calcium to patients with hyperkalemia and digoxin poisoning represents a clinical dilemma. Classic teaching is that in the setting of the increased intracellular calcium concentration from digoxin poisoning, administration of exogenous calcium will result in “stone heart” from excessive intracellular calcium. This concept has been in the literature since 1927, based primarily on animal studies. Documented cases of cardiac arrest after calcium administration are exceedingly rare in the literature, and the temporal relationship is dubious. More recent human data indicate that the IV administration of calcium for hyperkalemia in the setting of digoxin toxicity is safe. Unequivocally, however, the best treatment of hyperkalemia due to acute digoxin toxicity is Fab fragments. The treatment of hyperkalemia in a patient with chronic digoxin toxicity and renal failure is less clear; however, the evidence that calcium salts will be harmful in this scenario is lacking. Calcium salts should be administered over several minutes through a secure peripheral IV site or through a central venous catheter. Treatment of hyperkalemia related to digoxin toxicity is identical in indication and approach to that for hyperkalemia from other causes (see Chapter 117). Hypomagnesemia enhances the effects of cardioactive steroids. Therefore, any patient with suspected poisoning should have serum magnesium concentrations measured. This is further supported by evidence of magnesium reversing digoxin-induced tachydysrhythmias. If significant magnesium depletion is present or suspected (eg, electrocardiographic changes such as QTc prolongation are present), 1 to 2 g of magnesium sulfate should be administered over 10 to 20 minutes (child: 25 mg/kg), followed by a constant infusion of 1 to 2 g/hr until magnesium concentrations are normal. Patients should be closely monitored for respiratory depression, which is usually preceded by progressive loss of deep tendon reflexes. Infuse magnesium slowly and pause the infusion if heart block or bradycardia develops. Avoid magnesium in patients with renal failure. We do not recommend administration of magnesium in bradydysrhythmias and conduction blocks, because hypermagnesemia may impair impulse formation and AV conduction.

Atropine

Atropine is generally used for severe bradycardia and advanced AV block. We recommend using atropine as a temporizing measure for patients with shock while Fab fragments are being administered. We also recommend atropine for bradycardia refractory to Fab fragments. Standard dosing (0.02 mg/kg in children with a minimum of 0.1 mg; 1 mg IV in adults) should be used. Doses can be repeated every 3 to 5 minutes. In general, an external or transvenous pacemaker should be readied once atropine has been administered.

Pacing and Cardioversion

Transvenous pacing has been a mainstay of treatment for several decades; however, there is some evidence that the catheter may induce ventricular tachydysrhythmias in a myocardium made irritable by digoxin, although convincing studies on this question are lacking. Iatrogenic accidents of cardiac pacing are frequent (36%) in one study and can be fatal (up to 13%). Transvenous pacing should be used only if external pacing fails. Pacing usually is required only temporarily while waiting for Fab fragments to take clinical effect. Cardioversion in the setting of digoxin poisoning should be reserved for life-threatening dysrhythmias such as tachydysrhythmias with profound refractory hypotension, unstable ventricular tachycardia, or ventricular fibrillation.

Phenytoin and Lidocaine

Digoxin immune Fab fragments are the preferred therapy for dysrhythmias, but a dysrhythmia may require intervention while Fab fragments are readied, or to begin to show effect after infusion. Although both phenytoin and lidocaine are believed to be safe for control of tachydysrhythmias in the setting of digoxin toxicity, we prefer phenytoin. Indications for phenytoin include unstable tachydysrhythmias when Fab fragments are unavailable and unstable tachydysrhythmias that occur while waiting for Fab fragments to take effect. Phenytoin may enhance AV conduction. We recommend administering phenytoin in 100 mg boluses every 5 minutes until dysrhythmias improve or until the standard loading dose of 18 mg/kg is reached. No data exists to support or refute the substitution of fosphenytoin for phenytoin in this scenario. We recommend lidocaine only if the patient has a contraindication to phenytoin or if the maximum dose of phenytoin has been reached. When given, we recommend a loading dose of 1.5 mg/kg
IV push, followed by an infusion of 1 to 4 mg/min (30 to 50 µg/kg/min), started at 1 mg/min and titrated up based on response to therapy. Most other cardiovascular drugs (isoproterenol, procainamide, amiodarone, β-blockers, calcium antagonists) may worsen dysrhythmias or depress AV conduction in digoxin poisoned patients and should not be used.

**Pediatric Considerations**

Children with healthy hearts can tolerate massive acute oral ingestions without Fab treatment. This excludes therapeutic errors, children who are taking digoxin therapeutically, and children with heart disease. Dosage calculation and administration errors account for more pediatric digoxin intoxication and death than accidental oral ingestion. Therapeutic errors, especially accidental IV overdoses, often result in death within 1 to 4 hours.

Signs and symptoms in children with digoxin poisoning are different than adults (Table 147.2). Vomiting, somnolence, and obtundation are more common than in adults. Tachydysrhythmias as common as blocks and bradydysrhythmias are more common than in adults. Allergic reactions to Fab fragments are more common than in adults. Vd is less variable (5 to 7.5 L/kg) than in adults. Allergic reactions are more common (1% to 5%) that of propranolol.

**Disposition**

All patients who are symptomatic from digoxin toxicity with hyperkalemia, dysrhythmia, AV block, or significant comorbidity should be admitted to an intensive care or coronary care unit after treatment with Fab fragments. Asymptomatic patients reporting an acute ingestion of digoxin should be observed for at least 12 hours of continuous cardiac monitoring.

**BETA-ADRENERGIC BLOCKERS**

**Principles of Toxicity**

Beta-adrenergic blocking drugs became widely used in Europe in the 1960s for treatment of dysrhythmias. Their antihypertensive effects were later appreciated. By the 1970s, they were one of the most widely prescribed classes of drugs in the United States. Current indications include supraventricular dysrhythmias, hypertension (although the drugs have fallen out of favor for this indication), angina, thyrotoxicosis, migraine, and glaucoma. Of the numerous beta-blockers available, propranolol overdose is the most deadly. In 2013, United States poison centers received more than 24,000 calls regarding beta-blocker exposures. Nearly 1000 of these calls were regarding patients with life-threatening symptoms.

**Pathophysiology**

Beta-blockers structurally resemble isoproterenol, a pure β1 agonist. They competitively inhibit endogenous catecholamines such as epinephrine at β-adrenergic receptors, blocking the catecholamine effects of inotropy (increased myocardial contraction), dromotropy (enhanced cardiac conduction), and chronotropy (increased heart rate). These are all β1 effects. Complex β2 effects include vascular (smooth muscle relaxation and vasodilation), liver (glycogenolysis, gluconeogenesis), lung (bronchodilation), adipose tissue (release of free fatty acids), and uterus (smooth muscle relaxation) effects. Equally important properties, which vary from one beta-blocker to another, include cardioselectivity (β2 selectivity), membrane-stabilizing effect (fast cardiac sodium channel blocking properties), lipophilic, and intrinsic sympathomimetic activity (Table 147.2). Although cardioselectivity is lost in overdose, cardioselective beta-blockers such as atenolol, metoprolol, and esmolol still have a lower mortality rate than that of propranolol.

Beta-blockers are rapidly absorbed after oral ingestion, with peak effects varying between drugs. Hepatic metabolism on first pass results in significantly less bioavailability after oral dosing than with IV injection (eg, 1:40 for propranolol, 1:2.5 for metoprolol). Because volume of distribution for most beta-blockers generally exceeds 1 L/kg, hemodialysis is not efficacious for most beta-blockers. Protein binding varies from 0% for sotalol to 93% for propranolol. Elimination half-lives vary from 8 to 9 minutes for esmolol to as long as 24 hours for nadolol (see Table 147.3).

**Clinical Features**

The most common initial sign remains bradycardia. Hypotension and unconsciousness are the second and third most common signs (Box 147.8). Much of propranolol’s unique toxicity derives from its lipophilic nature, which allows it to penetrate the CNS, causing obtundation, respiratory depression, and—with large overdoses—seizures. Seizures probably result from a combination of hypotension, hypoglycemia, hypoxia, and direct CNS toxicity including sodium-channel blockade. Other beta-blockers are not lipophilic and do not have these effects. Of note, bronchospasm is rarely a problem in cases of beta-blocker overdose, even with nonselective β-blockers. The few cases of symptomatic bronchospasm respond to the usual bronchodilator nebulizations.

Propranolol, nadolol, betaxolol, and acebutolol have a membrane-stabilizing effect that impairs SA and AV node
function and leads to bradycardia and AV block. Ventricular conduction is also depressed, leading to QRS widening, occasional ventricular dysrhythmias such as ventricular tachycardia and ventricular fibrillation, and cardiogenic shock. The intrinsic sympathomimetic activity of some beta-blockers such as pindolol, oxprenolol, acebutolol, and carteolol can lead to some unusual manifestations such as ventricular dysrhythmias and sinus tachycardia instead of bradycardia. Labetalol and carvedilol also block $\alpha_1$-adrenergic receptors, giving an additional mechanism for hypotension and distributive shock. However, labetalol’s beta-blockade is three (oral route) to seven (IV route) times more potent than its $\alpha_1$-blockade. Carvedilol is even more beta-selective; its blockade of $\beta_1$ and $\beta_2$ receptors is 10 times more potent than $\alpha_1$. Nebivolol is a cardioselective beta-adrenergic blocker that also causes vasodilation through a unique mechanism: induction of endothelium-dependent vasodilation by stimulation of nitric oxide bioactivity.

In contrast to digoxin, beta-blocker toxicity has a more rapid onset. Life-threatening CNS and cardiovascular effects can occur 30 minutes after oral overdose. Patients ingesting delayed-release preparations may remain asymptomatic for several hours, followed by a prolonged period of toxicity up to 24 hours.

### Differential Diagnoses

The combination of bradycardia and hypotension suggests beta-blockade, calcium channel blockade, or digoxin poisoning. Centrally acting $\alpha_2$-adrenergic agonists such as clonidine and tizanidine or imidazoline receptor agonists such as tetrahydrozoline and oxymetazoline may also cause this constellation of symptoms. Without a history of beta-blocker ingestion, the diagnosis can be challenging, especially when non-cardiac effects such as CNS depression and seizures predominate. Sodium channel poisoning with QRS widening can occur, suggesting other antidysrhythmic drugs or cyclic antidepressants. The differential diagnosis also includes sedative-hypnotic drug overdose, hypoglycemic drug ingestion, opioid overdose, CNS injury or infection, endocrine-metabolic disorder, sepsis, and acute myocardial infarction.

### Diagnostic Testing

Diagnosis and management depend entirely on the clinical picture, and the only mandatory testing is in the form of a 12-lead electrocardiogram (ECG) and continuous ECG monitoring for rate, rhythm, and intervals. Blood concentrations of beta-blockers correlate poorly with severity of intoxication and are not readily available. Most urine toxicology screens do not identify antidysrhythmic drugs and are not helpful. Hypoglycemia is more common in children, and bedside determination of glucose concentration should be done if CNS depression is noted. Known access of the patient to a beta-blocker and consistent clinical features such as bradycardia and hypotension should lead the clinician to consider beta-blocker intoxication and begin empirical treatment. Whereas some authors believe that a serum lactate concentration can help predict mortality in overdose patients, this has not held true in pure beta-blocker ingestions.

### Management

Immediate measures include IV fluids, supplemental oxygen, and monitoring of cardiac rhythm and respirations.

Whole-bowel irrigation is cumbersome; and because there is a lack of evidence for efficacy in clinical trials, we recommend against its use in beta-blocker poisoning. The benefit of gastric lavage is also unproven, the procedure is cumbersome and benefit

likely is outweighed by procedural risks. Please see Chapter 139 for further information on gastrointestinal decontamination, including the use of activated charcoal.

Hypotension, Bradycardia, and Atrioventricular Block

The first step in the treatment of beta-blocker overdose is bolus administration of crystalloid fluids. In hypotensive patients, 20 to 40 mL/kg of normal saline or lactated Ringer’s solution can be infused and repeated once. Further doses of isotonic fluids, however, can lead to pulmonary edema and should be avoided particularly in older patients with cardiac disease. Atropine at standard doses noted earlier may be used for bradycardia but is rarely effective. We recommend atropine for a heart rate of less than 50 beats per minute with concomitant hypotension and symptoms of severe bradycardia such as weakness, drowsiness, or obtundation. Infusion of more potent drugs or cardiac pacing is often necessary; in fact, we recommend atropine is best used as a temporizing measure to the therapies noted later.

Calcium

The final common pathway for stimulation of beta-adrenergic receptors is an increase in intracellular calcium concentration, and deleterious effects on calcium transport may contribute to beta-blocker toxicity. Therefore, IV administration of calcium can be used for treatment of hypotension. One gram of calcium gluconate contains 4.5 mEq of elemental calcium, whereas 1 g of calcium chloride contains 13.6 mEq. Calcium chloride is an acidicifying salt and can cause significant tissue damage and necrosis if extravasation occurs. Thus it should be administered through a central venous catheter or a secure large-bore antecubital peripheral line if the patient is in extremis. Indications for calcium include hypotension unresponsive to crystalloid fluids and/or bradycardia; typically the heart rate should be less than 60 beats per minute, keeping in mind to consider if the patient has relative bradycardia. We recommend an initial dose of 13 to 25 mEq of calcium in adults (1 to 2 g calcium chloride, 3 to 6 g calcium gluconate) during 10 minutes. Patients in extremis may receive the initial dose during 1 minute. If a response is observed, repeated doses may be given in 20 minutes, and a constant infusion may be started at 20 mg/kg/hr of calcium chloride (60 mg/kg/hr of calcium gluconate). The total serum calcium level should be raised no higher than 14 mg/dL, which is the threshold of “severe” hypercalcemia. If ionized calcium is measured instead of total calcium, we recommend not to exceed 1.5 times the upper limit of normal. The serum calcium concentration can be as high as 18.2 mg/dL within 15 minutes after a bolus of just 5 mL of 10% calcium chloride, so calcium concentrations should be measured at least 30 minutes after bolus dosing has finished.

Glucagon

Glucagon has both inotropic and chronotropic effects and does not depend on beta-adrenergic receptors for its action; therefore, it has long been used for beta-blocker toxicity. It stimulates the production of intracellular cyclic adenosine monophosphate independently of the beta-adrenergic receptor. Furthermore, it helps counteract the hypoglycemia induced by beta-blocker overdose. Although not well studied, the initial dose of glucagon is a 5- to 10-mg IV bolus (0.05 to 0.1 mg/kg for children). If a response occurs to glucagon, specifically if heart rate, blood pressure, or symptom improvement is observed, the “response dose” should be started as an infusion at a rate of the response dose administered over 1 hour. We recommend glucagon for patients with bradycardia or hypotension not responsive to crystalloid fluids, atropine, and an initial bolus of calcium. Glucagon has a very short (20-minute) half-life, and its effect is often transient. Vomiting is a common complication of glucagon, particularly if administered too rapidly, so the airway should be secured or monitored closely to prevent aspiration. With cumulative large doses, glucagon should be diluted in 5% glucose in water for constant infusion. Side effects also include hypokalemia and allergic reactions. The response to glucagon alone is often inadequate, and glucagon is likely to be less effective than high-dose insulin (HDI) therapy. Furthermore, hospitals may not be adequately stocked for treatment beyond a few hours. From clinical experience, we find glucagon most useful as a transient therapy to bridge patients to HDI therapy.

High-Dose Insulin

Despite glucagon’s longer history for treatment of beta-blocker toxicity, HDI is a superior therapy. HDI is not a vasopressor; it is a profound inotrope with vasodilating properties. The mechanism for HDI is not fully elucidated but probably involves both optimization of the use of carbohydrates for fuel by cardiac myocytes and modulation of intracellular calcium. HDI improves cardiac output significantly in beta-blocker toxicity from an increase in stroke volume more than heart rate.11 Dosing of HDI is not agreed on; dosing in humans successfully treated with HDI has ranged from 0.5 to 22 U/kg/hr. In the largest human case series to date, of patients receiving HDI, 11 of 12 patients survived.12 Mean maximal HDI dosing in this series was 8.7 U/kg/hr. We recommend a bolus of 1 U/kg of regular insulin IV, followed by an infusion at 1 U/kg/hr titrated up by 2 U/kg/hr every 10 minutes until a maximum of 10 U/kg/hr is reached. Regardless of HDI dosing, we recommend that patients should receive a bolus of dextrose before insulin, and a dextrose infusion should be started thereafter as a bolus of 25 g glucose (1 traditional “amp” of D50) if the serum glucose concentration is below 200 mg/dL (11.1 mmol/L) followed by concentrated dextrose solutions such as D25, D50, or even D70 through a central line because patients receiving HDI therapy are at risk of fluid overload. Glucose concentration should be monitored as frequently as every 15 minutes until a steady state of glucose use is achieved. Potassium concentration should also be monitored closely and potassium replaced as needed because patients may become hypokalemic. We recommend HDI for patients experiencing hypotension despite crystalloid fluid, atropine, and a single bolus of calcium and glucagon. We also recommend a central venous catheter and an arterial catheter be placed immediately upon the decision to initiate HDI.

Sodium Bicarbonate

Sodium channel blockade from beta-blockers with membrane-stabilizing activity such as propranolol occasionally causes QRS widening, which mechanistically should respond to sodium bicarbonate. Bicarbonate should be dosed at 1 to 2 mEq/kg IV as a bolus repeated every 3 to 5 minutes until the QRS narrows to less than 120 ms. It is our experience this is typically a late or even moribund finding in propranolol overdose. We recommend sodium bicarbonate for patients poisoned with a membrane-stabilizing beta-blocker who have an acute change in QRS duration to greater than 120 ms and demonstrate clinical signs of shock.

Vasopressors and Other Inotropes

Catecholamines are indicated when mean arterial pressure (MAP) cannot be maintained at 60 mm Hg or above, despite use of crystalloid infusion, calcium, atropine, glucagon, and HDI. A single catecholamine of choice after HDI and glucagon has not emerged. Because norepinephrine appears to be superior to
dopamine for cardiogenic shock and does not carry any vaso- 
dilatory risk as many pure inotropes do, norepinephrine is our cate-
cholamine of choice when HDI is inadequate in maintaining MAP. In the selection of cardiacotropic medications to supplement HDI and glucagon, we recommend early assessment of cardiac contractility with bedside echocardiography. If contractility and heart rate is adequate, therapeutic focus should shift to providing support with vasopressors. Our second-line vasopressor of choice is vasopressin, dosed at a constant infusion of 0.04 U/min. If the clinical picture is still uncertain, systemic vascular resistance and cardiac output by either indirect or direct measurements is re-
commended to determine if either cardiogenic or distributive shock exists. We recommend third-line vasopressors be chosen based upon these measurements used along-side bedside echocar-
diography. Refractory cases of bradycardia may respond to an external or transvenous pacemaker. A pacemaker is particularly useful when cardiac contractility is vigorous but bradycardia is persistent.

**Intravenous Fat Emulsion (Intralipid)**

Intravenous fat emulsion (IFE) is a newer therapy option for poison-induced cardiogenic shock. This therapy was first described for treatment of toxicity from local anesthetics such as bupiva-
caine. The pharmacologic rationale for the use of IFE is discussed in Chapter 139. Of note, animal evidence exists to support the use of IFE for both lipid-soluble beta-blockers (such as propranolol) and non–lipid-soluble beta-blockers (such as atenolol). Human case reports of successful resuscitations of patients in extremis or arrest exist for propranolol, nebivolol, and metoprolol. Indica-
tions for IFE are not universally agreed upon. Although originally described as a treatment for overdose patients in cardiac arrest, several reports now exist describing the successful use of IFE in critically ill patients that still retain a pulse. IFE is a reason-
able therapy in beta-blocker overdose in patients with shock refractory to conventional treatments. We recommend IFE in patients with persistent bradycardia or hypotension not responding to IV fluids, calcium, HDI, and at least three vasopressors or inotropes at maximum recommended infusion rates. Dosing for IFE is also not universally agreed upon. We recommend an initial bolus of 1.5 mL/kg of 20% lipid solution given over 2 to 3 minutes, followed immediately by an infusion of 0.25 mL/kg/min. Based on pharmacokinetic modeling, some authors recommend decreasing the maintenance infusion to 0.025 mL/kg/min to sustain lipemic serum for a longer period of time. Such an approach, however, is not yet validated in human overdose patients. The 1.5 mL/kg bolus can be repeated up to two addi-
tional times for refractory shock or cardiac arrest, although clinicians should avoid exceeding the U.S. Food and Drug Admin-
istration (FDA) recommended lipid daily dose of 12.5 mL/kg unless hemodynamic compromise requires otherwise. Response, when it occurs, is typically within minutes of the bolus.

Despite recent enthusiasm for IFE, its use is not without associ-
ated complications, including extreme lipemia resulting in lab interfer-
ence with blood tests (complete blood counts, chemistries, and coagulations studies), as well as acute pancreatitis, and acute respiratory distress syndrome.

**Ventricular Dysrhythmias**

Although it is uncharacteristic, ventricular tachydysrhythmias can occur following beta-blocker toxicity. Cardioversion and defibril-
lation are indicated for ventricular tachycardia and ventricular fibrillation, respectively, following American Heart Association guidelines. Pulsatile ventricular tachycardia can most safely be treated with lidocaine. For dosing recommendations, please see the Management of Cardioactive Steroids section.

**Beta-Blockers That May Be Amenable to Hemodialysis**

- Sotalol
- Atenolol
- Timolol
- Acebutolol
- Nadolol

**Extracorporeal Elimination and Circulatory Assistance**

Hemodialysis or hemoperfusion may be beneficial for beta-
blockers with lower Vₐ, lower protein binding, and greater hydrophilicity (Box 147.9).

Unlike overdoses of other drugs, toxicity from cardiovascular drugs do not destroy tissue, and if circulation can be supported, complete recovery can be expected. An intra-aortic balloon pump or cardiopulmonary bypass can be lifesaving in cases of hypoten-
sion refractory to HDI multiple vasopressors and IFE. A percu-
aneous left ventricular assist device, in addition to extracorporeal membrane oxygenation (ECMO), have also been used to success-
fully resuscitate beta-blocker poisoned patients though this combination of therapies is unknown. ECMO alone is consid-
ered by some investigators to be a promising emerging therapy; however, no consensus guidelines exist. We recommend ECMO in cases where patients have hypotension refractory to HDI, at least three catecholamines, and IFE, or in cases with bradycardia unresponsive to inotropes and a pacemaker.

**Pediatric Considerations**

Severe pediatric beta-blocker poisonings are rare. In the cases reported, CNS, cardiac, and metabolic toxicities are similar. Symptomatic hypoglycemia, however, is more common in chil-
dren and occurs even after therapeutic doses. Therefore, serum glucose concentration should be measured in children. Risk factors include young age, fasting state, and diabetes mellitus. Obtunded children should receive empirical glucose, 1 to 2 mL/kg of 25% glucose IV. In general, 5% glucose infusions have been sufficient to maintain euglycemia, especially with concomi-
ant use of glucagon and catecholamines, which stimulate glucose release.

Seizures also occur in cases of pediatric beta-blocker overdose, but hypoglycemia is probably an important contributing factor. They are more common with the lipid-soluble beta-blockers propranolol. Benzodiazepines are generally effective.

Children generally fare well after beta-blocker ingestion, with symptoms in only 2% of potential beta-blocker exposures in children.

**Sequential Approach to Beta-Blocker Poisoning**

The management of beta-blocker poisoning begins with a 20 mL/kg bolus of IV fluid, repeated once if needed (Box 147.10).
Symptomatic bradycardia, typically a heart rate of 60 bpm or less in adults, should be treated with atropine, 0.5 mg every 3 minutes up to total of 3 mg. If hypotension (a systolic pressure <90 mm Hg) persists, 3 to 6 g of calcium gluconate should be infused over 10 minutes. If hypotension persists after calcium infusion, HDI should be initiated. Glucagon, given as a 5-mg bolus, can be used to bridge to HDI. One “amp” of D50 should be administered followed by 1 U/kg of regular insulin as a loading dose. An infusion of 25 g/hr of concentrated glucose should be initiated in addition to an infusion of insulin at 1 U/kg/hr. The insulin infusion should be increased by 2 U/kg/hr every 10 minutes until hypotension resolves or a maximum rate of 10 U/kg/hr is reached. Glucagon may be repeated during HDI titration if hypotension persists. If HDI does not resolve hypotension, norepinephrine should be administered starting at 0.1 mcg/kg/min and titrated up until hypotension resolves or until a maximum dose is reached. After maximal norepinephrine is reached, the clinician should reassess using bedside echocardiography and measurement of cardiac output and systemic vascular resistance to determine if the patient needs additional inotropy, chronotropy, or vasotropy. If bradycardia is contributing to decreased cardiac output, we recommend a transvenous pacemaker. Additional inotropes and/or vasopressors such as vasopressin, phenylephrine, epinephrine, dopamine, or dobutamine should be selected and titrated up based upon the patient’s cardiac output and systemic vascular resistance. We recommend vasopressin as the second-line vasopressor at a steady-state infusion of 0.04 U/min. Once the patient has reached maximal doses on HDI and three vasopressors or catecholamines, we next recommend IFE at 1.5 mL/kg IV of 20% lipid solution followed by an infusion of 0.25 mL/kg/min. The bolus may be repeated; however, a maximal dose of 1000 mL of lipid solution should not be exceeded. If the patient continues to have hypotension or bradycardia refractory to all the aforementioned therapies, extracorporeal support should be initiated. We recommend ECMO; although cardiopulmonary bypass, an intra-aortic balloon pump, or a percutaneous left-ventricular assist device would be reasonable if ECMO is not immediately available. Downward titration of infusions for beta-blocker poisoning rarely occurs in the emergency department.

**Disposition**

Patients who remain completely asymptomatic for 6 hours after an oral overdose of normal-release preparations can be safely referred for psychiatric evaluation. We recommend consultation with a poison control center or standard pharmacologic reference to confirm that peak effect of the beta-blocker in question has passed before psychiatric disposition. Patients ingesting sustained-release preparations should be admitted to a monitored bed; however, those who remain asymptomatic 8 to 12 hours after ingestion are very unlikely to have toxicity. Patients with second or third degree heart block, hypotension not responding to IV fluid administration, or who have hemodynamically significant dysrhythmias should be admitted to an intensive care unit.

**CALCIUM CHANNEL BLOCKERS**

**Principles of Toxicity**

Verapamil and nifedipine, the earliest calcium channel antagonists, were introduced in Europe in the 1970s and in the United States in the early 1980s. Calcium antagonists have found many clinical applications: angina pectoris, hypertension, supraventricular dysrhythmias, hypertrophic cardiomyopathy, and migraine prophylaxis. Most fatalities occur with verapamil, but severe toxicity and death have been reported for most drugs of this class. In 2013, United States poison control centers received more than 11,000 calls about calcium channel blockers. Nearly 500 of these calls were regarding patients with life-threatening symptoms.

**Pathophysiology**

Calcium channel antagonists block the slow L-type calcium channels in the myocardium and vascular smooth muscle, leading to coronary and peripheral vasodilation. They also reduce cardiac contractility, depress SA nodal activity, and slow AV conduction. In cases of overdose, verapamil has the deadliest profile, combining severe myocardial depression and peripheral vasodilation. Both verapamil and diltiazem act on the heart and blood vessels, whereas dihydropyridine calcium channel blockers (such as nifedipine) cause primarily vasodilation and subsequent reflex tachycardia. As with beta-blockers, selectivity is lost after overdose, and toxicity is fourfold; the calcium antagonists have negative effects on heart rate, contractility, conduction, and vascular tone, with the exception of dihydropyridine calcium channel blockers, which tend to result in tachycardia even in severe toxicity.

All calcium channel blockers are rapidly absorbed, although first-pass hepatic metabolism significantly reduces bioavailability (Table 147.4). Onset of action and toxicity ranges from less than 30 minutes to 60 minutes. Peak effect of nifedipine can occur as early as 20 minutes after ingestion, but peak effect of sustained-release verapamil can be delayed beyond 12 hours. High protein binding and V_d greater than 1 to 2 L/kg make hemodialysis or hemoperfusion ineffective. With sustained-release preparations, their half-lives are relatively short, generally limiting toxicity to 24 to 36 hours.

**Clinical Features**

Severe calcium antagonism eventually affects multiple organ systems, but cardiovascular toxicity is primarily responsible for morbidity and mortality. Hypotension and bradycardia occur early, and other rhythm disturbances include AV block of all degrees, sinus arrest, AV dissociation, junctional rhythm, and asystole. Dihydropyridine calcium channel blockers (such as

**Box 147.11**

**Manifestations of Calcium Channel Blocker Poisoning**

**Cardiovascular:** Hypotension, sinus bradycardia, sinus arrest, AV block, AV dissociation, junctional rhythm, asystole; ventricular dysrhythmias uncommon except with bepridil

**Pulmonary:** Respiratory depression, apnea; pulmonary edema; adult respiratory distress syndrome

**Gastrointestinal:** Nausea, vomiting, bowel infarction (rare)

**Neurologic:** Lethargy, confusion, slurred speech, coma; seizures (uncommon); cerebral infarction (rare)

**Metabolic:** Metabolic (lactic) acidosis; hyperglycemia (mild); hyperkalemia (mild)

**Dermatologic:** Flushing, diaphoresis, pallor, peripheral cyanosis

**AV, Atrioventricular.**

An ECG should be promptly obtained, with special attention to atrial and ventricular rates and PR, QRS, and QT intervals. The ECG is repeated when hemodynamic status changes. Like the beta-blockers, calcium antagonists cause early toxicity, and symptoms can be expected within 6 hours of ingestion of normal-release preparations. Toxicity can be delayed 12 to 24 hours with sustained-release preparations.

**Management**

Initial management includes rapid establishment of vascular access, cardiac monitoring, and frequent blood pressure measurement. Please see Chapter 139 for further information on gastrointestinal decontamination, including the use of activated charcoal. For an algorithmic approach to management, see Box 147.12.

**Hypotension and Bradycardia**

Hypotension can be caused by myocardial depression, inadequate heart rate, or peripheral vasodilation. Atropine may be used for bradycardia but is rarely effective. We recommend atropine at the...
is also a vasoconstrictor. Specifically, it inhibits the enzyme gua

tance. Methylene blue is particularly intriguing to use in the
muscle relaxation, causing an increase in systemic vascular resis-
tantly causes an increase in nitric oxide production, which leads
to increased cGMP and vasodilation as noted earlier. Data are

cally causes an increase in nitric oxide production, which leads

to increased cGMP and vasodilation as noted earlier. Data are

cally causes an increase in nitric oxide production, which leads

metabolic effects as opposed to mortality. We recommend the use of
methylene blue only as an alternative salvage therapy to ECMO
when HDI, catecholamines, and IFE have failed. Dosing involves
a 1- to 2-mg/kg bolus of a 1% methylene blue solution followed
by an infusion of 1 mg/kg for up to 6 hours.

Pediatric Considerations
Nifedipine, verapamil, and probably other drugs in its class join
the short list of medications that can kill a child with ingestion of
a single tablet. Seizures may be more common in children than in
adults and should be treated with diazepam, lorazepam, or
phenobarbital.

Overall, death after calcium antagonist ingestion in children is
rare. The IV route of administration, as with digoxin, is much
more dangerous. Even therapeutic doses of IV verapamil are
considered contraindicated in infants with supraventricular

tachycardia because of case reports of cardiovascular collapse and

cardiac arrest after injection.

Hyperglycemia occasionally occurs in children, but the eleva-
tion is usually short-lived. Although insulin has been adminis-
tered in a small number of cases, it is generally not necessary unless HDI
is required for hemodynamic compromise, because the hypergly-
cemia usually resolves spontaneously within 24 to 36 hours.

Case reports of children in refractory shock secondary to drug
toxicity have been treated with intra-aortic balloon counterpulsu-
tion or cardiac bypass. Circulatory support during the day or two
required for hepatic or renal elimination of the drug is potentially
beneficial for a drug that does not cause irreversible damage.

Aside from the differences previously noted, the presentation in
children is similar to that in adults: rapid onset of toxicity with
CNS depression, bradydysrhythmias (except for dihydropyridine
calcium channel blockers), and hypotension.

For an algorithmic approach to calcium channel blocker poi-
soning, please reference the sequential approach to beta-blocker
poisoning earlier, with the following exceptions. Glucagon is not
recommended, and methylene blue is recommended prior to
initiation of ECMO.

Disposition
Because the peak effect of normal-release calcium channel block-
ers commonly occurs in 90 minutes to 6 hours, patients who are
totally asymptomatic for 6 hours after an ingestion of immediate-release medication can be safely discharged according
to psychiatric needs. Symptomatic patients or those who ingested
delayed-release preparations should be admitted to a medical or
toxicology service for at least 24 hours of continuous cardiac
monitoring. Persistently hypotensive, bradycardic patients who
do not respond to conventional therapy require intensive care
monitoring.

CLONIDINE

Principles of Toxicity
Clonidine is a central acting α2-adrenergic and imidazoline
agonist initially approved by the FDA as a treatment for hyperten-
sion in 1974. Since that time, its use has expanded to treat condi-
tions such as attention-deficit/hyperactivity disorder (ADHD),
phenoxybenzamine, and withdrawal from opioids, ethanol, and
nicotine. It is also used in spinal and epidural anesthesia. Based
on its mechanism of action, it mimics clinical features of both
opioid poisoning and poisoning from digoxin, beta-blockers, or
calcium channel blockers. In 2013 United States poison centers
received over 9400 calls regarding clonidine exposures with over
1500 suffering life-threatening effects.

Clinical Features
Clonidine exerts its effects by binding to pre-synaptic α2-adrenergic
receptors in the brain, inhibiting neurons in the nucleus tractus
solitaries, causing decreased norepinephrine release. This leads to

bradycardia, hypotension, decreased mental status, miosis, and occasionally hypothermia. Clonidine is also an agonist at imidazolé receptors; imidazoline receptors are located throughout the body, but their activation in the brain, specifically in the rostral ventrolateral medulla, causes unconsciousness, bradycardia, and hypotension, potentially exacerbating the α2-adrenergic effects of clonidine.25

Differential Diagnosis

There is great overlap between the clinical effects of central α2-agonists such as clonidine and imidazoline agonists. Individual drugs that are agonists at either or both receptors may belong to disparate classes. Therefore, antihypertensive medications (such as guanabenz and alpha-methyldopa, ADH medications (such as guanafacine), muscle relaxers (such as tizanidine), and topical vasoconstrictors (such as tetrahydrozoline, oxymetazoline, and naprazoline) all have similar systemic effects in overdose. The presentation of miosis and obtundation may be mistaken for opioid or sedative-hypnotic overdose, and the combination of bradycardia and hypotension may mimic digoxin, beta-blocker, or calcium channel blocker poisoning. Pontine hemorrhage should also be considered in the differential diagnosis.

Diagnostic Testing

Clonidine and other similar drugs are not routinely screened for in most blood or urine drug screens. Clonidine poisoning is a clinical diagnosis. An ECG should be obtained to evaluate for heart block and to evaluate the QRS and corrected QT (QTc) intervals, and the patient should be placed on continuous cardiac monitoring and pulse oximetry. Small doses of naloxone may help differentiate clonidine poisoning from opioid poisoning; however if large doses are required, this may be less helpful diagnostically because large doses of naloxone have been reported to reverse clonidine toxicity.

Management

Supportive care is the mainstay of therapy for clonidine poisoning. Monitoring as described earlier is essential. Hypotension should be treated with boluses of 20 mL/kg of isotonic fluid. The concern for pulmonary edema is less than with beta-blocker or calcium channel blocker poisoning, thus the clinician should make more liberal use of IV fluids in clonidine poisoning. We recommend treating hypotension with up to 60 mL/kg of isotonic fluid. If hypotension is worsening or persistent at a level of inadequate organ perfusion despite adequate fluid resuscitation, a catecholamine is indicated. There are no human randomized trials comparing various catecholamines in clonidine poisoning; however, because the underlying pathophysiology is a lack of systemic norepinephrine, we recommend norepinephrine in this setting. Norepinephrine is initiated as 0.1 mcg/kg/min and titrated to a MAP of 60. When blood pressure stabilizes, downward titration of norepinephrine is initiated, with a goal to maintaining adequate organ perfusion with the least necessary dose, ultimately weaning the patient entirely.

Several authors have suggested naloxone may be a useful therapy in clonidine poisoning. As endogenous opioids do play a role in the central neurotransmission of norepinephrine, there is a physiologically plausible reason naloxone may be effective for clonidine poisoning. Although case reports of naloxone successfully reversing clonidine poisoning exist, they are rare. Our clinical experience is that naloxone is rarely effective for clonidine poisoning. Nevertheless, as side effects of judicious naloxone use are rare, steadily increasing doses of naloxone are a reasonable therapy for clonidine poisoning. If time and airway patency allows, we recommend escalating doses of naloxone of 0.1 mg, 0.4 mg, 2 mg, and 10 mg. Naloxone is indicated solely if the patient is obtunded or has an unprotected airway, and it should be administered in parallel with any necessary IV fluids or catecholamines.

Disposition

Clonidine’s peak effects occur 2 to 4 hours post-ingestion. Its half-life is between 5 and 13 hours. Therefore patients with normal vital signs and mental status 4 hours post-ingestion may be discharged home or to an appropriate psychiatric facility. Patients with persistent vital sign abnormalities or altered mental status should be admitted to a unit capable of continuous cardiac and oximetry monitoring. Patients requiring vasopressor support or with severe obtundation should be admitted to a critical care unit.

NITRATES AND NITRITES

Principles of Toxicity

Nitrates (nitroglycerin, isosorbide mononitrate, and dinitrate) are widely used as vasodilators in the treatment of heart failure and ischemic heart disease. They augment coronary blood flow, as well as reduce myocardial oxygen consumption by reducing afterload. At lower doses nitrates primarily dilate veins, but at higher doses they also dilate arteries. In addition, many exposures occur in young adults, usually male, who inhale various alkyl nitrates (amyl, butyl, isobutyl, or ethyl nitrite) in the hope of enhancing or prolonging sexual pleasure. Because of the sound they make when broken open, these products are best known to abusers as “poppers.”27 The popularity of poppers has waned in recent years as sales of sildenafil and related products have soared.

Nitrates are occasionally found in rural well water contaminated by livestock or fertilizer runoff. Oral nitrates may be converted to nitrates in the gastrointestinal tract, especially in infants up to 4 months old. Nitrates, and to a lesser extent, nitrates themselves, have substantial oxidizing power and may oxidize the ferrous (Fe2+) ion in hemoglobin to its ferric (Fe3+) state causing methemoglobinemia. Methemoglobin is incapable of carrying oxygen, thus it alters the shape of the hemoglobin-dissociation curve shifting it to the left, causing functional anemia via impaired oxygen delivery.

Clinical Features

Hypotension is a common complication. Typically it is accompanied by reflex tachycardia unless the patient also has taken another agent such as a beta-blocker that slows chronotropy. Rapid dilation of meningeal arterioles causes headache.

Patients suffering methemoglobinemia have symptoms related to impaired oxygen delivery. The concentration of methemoglobin and the speed with which the condition is contracted are related to symptom severity. The higher the concentration of methemoglobinemia and the speed with which it is achieved are proportional to symptom severity. Cyanosis occurs commonly if the percentage of methemoglobin exceeds 10%. Inspection of the patient’s blood upon venipuncture reveals “chocolate-colored” blood due to the spectrum of light absorbed by methemoglobin; this typically occurs at a methemoglobin concentration greater than 15%. Higher concentrations of methemoglobin may result in fatigue, dyspnea, weakness, dizziness, drowsiness, coma, seizures, and death.

Differential Diagnosis

The differential diagnosis of nitrate poisoning includes all other vasodilating drugs such as diuretics, angiotensin-converting
enzyme (ACE) inhibitors, and dihydropyridine calcium channel blockers, as well as oxidative phosphorylation uncouplers such as cyanide. Non-toxicologic conditions capable of mimicking nitrate poisoning include sepsis and anaphylaxis. The differential diagnosis of methemoglobinemia includes hypoxia, as well as other hemoglobinopathies such as sulfhemoglobinemia.

**Diagnostic Testing**

No specific diagnostic testing is recommended for nitrate poisoning. For patients with suspected methemoglobinemia, an oxygen challenge should first be attempted. If the patient is cyanotic and high flow oxygen at 15 L/min by non-rebreather mask does not improve cyanosis, blood co-oximetry should be performed to determine the percentage of methemoglobin in the blood. If methemoglobinemia is confirmed, a hemoglobin concentration should be obtained. If anemia is present, smaller concentrations of methemoglobin may be clinically significant because the functional anemia of methemoglobinemia is synergistic with absolute anemia. It should be noted most humans have, at baseline, a methemoglobin percentage of 1% to 3%. Symptoms do not typically occur until concentrations of 10% or more.

Clinicians should be wary of interpreting pulse-oximetry in the setting of methemoglobinemia. Pulse oximeters function by reading the absorbance of light at wavelengths of 660 and 940 nm, which are selected to separate oxy and deoxyhemoglobin. Methemoglobin absorbs light at both these wavelengths more than either oxy or deoxyhemoglobin. This results in unreliable pulse oximetry that typically reads between 75% and 85%, regardless of the patient’s oxygenation status.²⁸

**Management**

Nitrate poisoning usually responds to supine positioning, IV fluids, and reduction of dose or removal of the offending agent. Hypotension is usually transient. Low-dose vasopressors are occasionally needed, but it is best to avoid them in the setting of acute coronary syndrome.

Review of the therapeutic use of nitrates offers insight into poisoning. For example, IV nitroglycerin infusions are used commonly in patients with acute pulmonary edema for afterload reduction. Infusions are usually initiated at 5 to 10 µg/min, but rates as high as 200 to 300 µg/min may be used. These doses may be beneficial in patients with pulmonary edema accompanied by acute hypertension, but hypotension may develop suddenly. IV nitroglycerin has a rapid offset of action, so excessive fall in blood pressure usually responds to reduction or termination of the infusion. Use of nitrates is contraindicated in patients who have recently taken sildenafil (Viagra). Sildenafil and related drugs (vardenafil [Levitra] and tadafal [Cialis]) inhibit type 5 phosphodiesterase, relaxing vascular smooth muscle. These agents can prolong and intensify the vasodilating effects of nitrates, resulting in severe hypotension. If blood pressure does not normalize with IV fluids and cessation of the nitrate infusion, norepinephrine should be cautiously titrated to a MAP of 60, beginning at 0.1 mcg/kg/min.

Treatment of patients with methemoglobinemia involves supportive care such as supplemental oxygen and IV fluids. More severely poisoned patients should be treated with IV methylene blue. Methylene blue is an oxidizing agent. However, in the presence of the red blood cell enzyme nicotinamide adenine dinucleotide phosphate (NADPH) methemoglobin reductase, it is reduced to leukomethylene blue, which then reduces methemoglobin back to hemoglobin. We recommend an intravenous dose of 1–2 mg/kg of 1% methylene blue solution for patients with a methemoglobin concentration greater than 25% and any symptoms of functional anemia. The infusion should be given over 5 minutes to reduce pain at the IV site. A clinical response should occur within minutes of infusion. If cyanosis does not resolve in 1 hour, a second infusion of 1 mg/kg can be repeated. At doses exceeding 7 mg/kg, the oxidizing power of methylene blue becomes great enough that it may in fact worsen methemoglobinemia, thus patients receiving multiple doses should be monitored closely.

**KEY CONCEPTS**

**Cardioactive Steroids**
- Digoxin toxicity is often occult and should be considered in any patient who is on digoxin and presents with gastrointestinal or visual disturbance and a new dysrhythmia or conduction disturbance.
- Digitalis Fab is the specific antidote for digoxin toxicity and is dosed by body load of digitalis, not by body weight of the patient.
- Indications for digitalis Fab are summarized in Box 147.4, and Fab should be used before pacing or antidysrhythmics drugs.
- Hyperkalemia in acute digitalis toxicity is best treated with Fab fragments. Conventional treatment as for any other cause of hyperkalemia is also appropriate when Fab fragment preparations are not immediately available.

**Beta-Adrenergic Blockers**
- Beta-blocker intoxication usually causes bradydysrhythmias and occasionally AV block.
- Noncardiac symptoms such as obtundation, seizures, and hypoglycemia may occur, especially early in the course and particularly with propranolol.
- Volume expansion, atropine, calcium, and glucagon are early treatment measures, but absent a response, begin a HDI/glucose infusion.

**Calcium Channel Blockers**
- Signs and symptoms of calcium channel blocker intoxication often occur early after overdose but may be significantly delayed with sustained release products.
- AV block and bradydysrhythmias predominate with verapamil and diltiazem; dihydropyridine calcium channel blockers often present with tachycardia.

**Clonidine**
- Clonidine poisoning may mimic opioid poisoning and is best treated with crystalloid fluids followed by an infusion of norepinephrine.

**Nitrates, Nitrites, and Methemoglobinemia**
- Nitrates are contraindicated in patients who have recently taken phosphodiesterase inhibitors for erectile dysfunction.
- Patients with a methemoglobin concentration of 25% and symptoms of anemia should be treated with methylene blue.

---

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
147.4. A 5-year-old girl presents after taking some of her grandmother's heart medications. She has sinus bradycardia and a slightly low blood pressure. The remainder of her vital signs and physical examination are normal. He has a past medical history significant for myocardial infarction, congestive heart failure, hypertension, and diabetes. He states that he takes all prescribed medications regularly and just took all of his medications as prescribed approximately 1 hour ago. Reviewing his medication list, you note that one of his medications is digoxin. Which of the following should be done?

A. Administer oral potassium.
B. Give digoxin-specific Fab fragment antibodies now.
C. Give digoxin-specific Fab fragment antibodies only if he has an abnormal electrocardiogram (ECG).
D. Obtain a serum digoxin level in 6 hours.
E. Obtain a serum digoxin level now.

Answer: D. Ingestion of oleander (Nerium oleander)

E. Serum potassium greater than 5 mEq/L.

Answer: E. Hyperkalemia is an indication for treatment with digitalis antibody fragments. Other indications include severe ventricular dysrhythmias; hemodynamically significant bradydysrhythmias unresponsive to atropine; rapidly progressive rhythm disturbances or rising potassium level; co-ingestion of cardioactive drugs such as beta-blockers, calcium channel blockers, or cyclic antidepressants; or ingestion of a plant known to contain cardiac glycosides in the setting of severe dysrhythmias.

147.3. A 27-year-old man presents after ingesting 8 mg of digoxin in a suicide attempt. He has ventricular tachycardia on his electrocardiogram (ECG). His blood pressure is 93/54 mm Hg. Laboratory results are not available. You decide to treat with digitalis antibody fragments. How many vials should be given to bind the entire ingestion?

A. 2 vials
B. 4 vials
C. 8 vials
D. 16 vials
E. 20 vials

Answer: D. Each vial contains enough digitalis antibody fragments to neutralize 0.5 mg of digoxin; therefore the patient should be given 16 vials of Fab fragments to fully treat his ingested dose.

147.2. In a patient with a known digoxin overdose, which of the following is an indication for administration of digitalis antibody fragments?

A. Acute ingestion of 10 mg of digoxin
B. Atrial fibrillation with rapid ventricular response
C. First-degree heart block

D. Ingestion of oleander (Nerium oleander)

E. Serum potassium greater than 5 mEq/L.

Answer: A. Acute ingestion of 10 mg of digoxin

147.1. A 72-year-old man presents with a chief complaint of nausea. He also complains of blurred vision and general weakness. His vital signs and physical examination are normal. He has a past medical history significant for myocardial infarction, congestive heart failure, hypertension, and diabetes. He states that he takes all prescribed medications regularly and just took all of his medications as prescribed approximately 1 hour ago. Reviewing his medication list, you note that one of his medications is digoxin. Which of the following should be done?

A. Administer oral potassium.
B. Give digoxin-specific Fab fragment antibodies now.
C. Give digoxin-specific Fab fragment antibodies only if he has an abnormal electrocardiogram (ECG).
D. Obtain a serum digoxin level in 6 hours.
E. Obtain a serum digoxin level now.

Answer: D. Ingestion of oleander (Nerium oleander)
therapeutic intervention that is likely to treat both the endocrine and cardiovascular pathology would be:

A. Dobutamine
B. Epinephrine
C. High-dose insulin (HDI)
D. Intravenous fat emulsion (IFE)
E. Glucagon

**Answer:** C. Calcium channel blocker toxicity may result in bradycardia and hypotension, much like beta-blocker toxicity. Unlike beta-blocker toxicity, which can cause hypoglycemia, calcium channel blockers can cause hyperglycemia via blockade of calcium channels on beta islet cells. HDI therapy treats calcium channel blocker toxicity via increasing inotropy, as well as normalizing glucose.

**147.5.** A 60-year-old man has taken an overdose of his beta-blocker medication. He is awake and alert but has a pulse of 50 beats per minute and a blood pressure of 92/60 mm Hg. Which of the following is the most appropriate initial treatment?

A. Atropine, crystalloid fluids, calcium salts, glucagon
B. Atropine, crystalloid fluids, insulin
C. Atropine, dopamine, glucagon
D. Dopamine, crystalloid fluids, insulin
E. Dopamine, glucagon, insulin

**Answer:** A. Atropine, crystalloid fluids, calcium salts and glucagon are the initial treatments of choice for beta-blocker toxicity. If these agents are ineffective, high-dose insulin (HDI) is reasonable as next-line therapy for cardiogenic shock. If HDI is ineffective, catecholamines are a reasonable option. The catecholamine choice may vary depending on the type of shock the patient is in, and the dose needed for a response may be greater than for other conditions.

**147.6.** A patient presents after an apparent overdose of diltiazem. Which of the following findings would lead you to suspect a co-ingestant in addition to the calcium channel blocker?

A. Atrioventricular (AV) block on electrocardiogram (ECG)
B. Hyperglycemia
C. Metabolic acidosis
D. Prolonged QRS complex on ECG
E. Respiratory depression

**Answer:** D. Prolonged QRS and QT intervals are generally not seen in calcium channel blocker overdose and should prompt the search for co-ingestants. One exception is the calcium channel blocker bepridil, which can cause QRS or QT prolongation. All the other listed abnormalities are typical of calcium channel blocker overdose.

**147.7.** Treatment for an overdose of beta-blockers is most similar to the treatment for an overdose of which other class of medication?

A. Anticholinergics
B. Calcium channel blockers
C. Cyclic antidepressants
D. Digoxin
E. Nitrates

**Answer:** B. Symptoms from overdose of calcium channel blockers and beta-blockers are similar, as are the therapeutic strategies. Severe anticholinergic toxicity may respond to physostigmine administration, cyclic antidepressants to intravenous (IV) sodium bicarbonate boluses, digoxin poisoning to antibody Fab fragments, and nitrate toxicity to methylene blue therapy.

**147.8.** Which of the following drugs can kill a toddler with ingestion of a single tablet?

A. Atenolol
B. Chlorthalidone
C. Lisinopril
D. Nitroglycerin
E. Verapamil

**Answer:** E. Verapamil and other calcium channel blockers can kill a toddler with the ingestion of a single tablet. Appropriate medical treatment, however, is extremely effective, and very few children die from calcium channel blocker overdose. Although beta-blockers have the potential to cause serious toxicity, propranolol is the beta-blocker most likely to cause serious toxicity. Educating parents and caregivers of young children about the potential effects of these medications is important.
CHAPTER 148

Caustics

Christopher Hoyte

PRINCIPLES OF TOXICITY

Caustic or corrosive agents have the potential to cause tissue injury on contact with mucosal surfaces. Both strong acids and alkalis are capable of causing corrosive chemical injury. Alkalis are proton acceptors and result in the formation of conjugate bases and free hydroxide ions. Lye is an example of an alkali and refers to both sodium hydroxide (NaOH) and potassium hydroxide (KOH). Ammonia (NH₃) is another common alkaline corrosive. Acids are proton donors; they dissociate into conjugate bases and free hydrogen ions in solution. Acidic caustics include hydrochloric acid (HCl) and sulfuric acid (H₂SO₄). The injury from caustic agents typically increases with a pH below 3 or above 11. Other chemicals that have caustic properties include phenol, formaldehyde, iodine, and concentrated hydrogen peroxide. This chapter discusses oral exposure. Dermal and inhalational exposures are discussed in Chapter 57 and Chapter 155, respectively.

More than 40,000 exposures involving caustic agents occur in the United States every year. Nearly 75% of reported caustic ingestions are intentional for the purpose of self-harm. Accidental ingestions occur typically among pediatric and elderly populations. Transfer and storage of cleaners in alternative containers that may not be "child proof," such as jars, soda, and sports drinks, may cause unintentional ingestion. Intentional ingestions may have a greater degree of oropharyngeal sparing because of rapid swallowing but have a higher likelihood of serious injury.

Some household products, such as liquid drain cleaners, contain high concentrations of alkali (30% KOH) or acid (93% H₂SO₄) (Table 148.1). These products often do not have concentration or content information available on the label, making it difficult for clinicians to determine the severity of exposure. Industrial, farm (dairy pipeline cleaners containing liquid NaOH and KOH in concentrations of 8% to 25%), and swimming pool chemicals also contain caustics in high concentrations.

Crystals and solid particles can have prolonged tissue adherence, causing more severe injury. These ingestions are limited by immediate oral pain, usually causing the ingested agent to be spit out sooner than a liquid agent. The ingestion of granular automatic dishwasher detergents or brightly colored laundry detergent capsules or "pods" can be associated with devastating injuries. Crystal drain cleaners have lye concentration as high as 74% NaOH and may cause proximal esophageal injury. Liquid dishwashing detergents and laundry detergents have a pH higher than 12, but because the titratable alkaline reserve is low, tissue equilibration occurs quickly, and there is less risk of injury after ingestion.

Liquid household bleach typically contains dilute (3% to 5%) sodium hypochlorite (NaOCl), and ingestion rarely causes consequential injury. Industrial-strength bleach, however, contains significantly higher concentrations of NaOCl, which are more likely to cause esophageal necrosis. Toilet bowl cleaners contain HCl as high as 26%. General-purpose anticorrosive cleaners, such as 31% muriatic acid (HCl), are sold in gallon containers for home use and as swimming pool cleaners.

The alkali powder in air bags can cause ocular burns. Perfume unintentionally sprayed into the eyes can be caustic. Cement is alkaline and causes topical burns, typically on the knees and hands. Although hair relaxer creams contain NaOH and have a pH of 11.2 to 11.9, injuries after ingestion are usually mild.

Caustic ingestions may occur when methamphetamine is produced from over-the-counter medications and household chemicals. H₂SO₄, HCl, NaOH, ammonium hydroxide, anhydrous ammonia, and metallic lithium are all used in the clandestine production of methamphetamine. Severe caustic injuries occurring from ingestion of these agents can cause stricture formation, esophageal resection, and the need for colonic interposition.

Many medication pills can cause injury when they come in contact with esophageal mucus for prolonged periods. Patients who take medications in the supine position or who take pills without water are at higher risk of pill esophagitis. The pills most likely to adhere are doxycycline, tetracycline, potassium chloride, and aspirin. Although uncommon, potassium chloride is particularly dangerous and can cause esophageal perforation with devastating communication with the aorta, left atrium, and bronchial artery.

Factors that influence the extent of injury from a caustic exposure include type of agent, concentration of solution, volume, viscosity, duration of contact, pH, and presence or absence of food in the stomach. The titratable acid/alkaline reserve of an alkali or acid correlates with the ability to produce tissue damage. Concentrated forms of acids and bases generate heat, resulting in superimposed thermal injury.

Acidic compounds desiccate epithelial cells and cause coagulation necrosis. An eschar is formed that limits further penetration. Because acids tend to have a strong odor and cause immediate pain on contact, the quantity ingested is usually limited. Because of resistance of squamous epithelium to coagulation necrosis, acids are thought to be less likely to cause esophageal and pharyngeal injury, although severe esophageal and laryngeal injury still occur particularly with intentional ingestions. In many cases, acid ingestion results in equal esophageal and gastric mucosal injury. Acids can also be absorbed systemically, causing metabolic acidosis as well as damage to the spleen, liver, biliary tract, pancreas, and kidneys from perforation and direct local contact.

Alkaline contact, in contrast to acids, causes liquefaction necrosis, fat saponification, and protein disruption, allowing further penetration of the alkaline substance into the tissue. The depth of the necrosis depends on the concentration of the agent. A concentration of 30% NaOH in contact with tissue for 1 second results in a full-thickness burn. Alkalis are colorless and odorless, and unlike acids, they do not cause immediate pain on contact. Alkaline ingestions typically involve the squamous epithelial cells of the oropharynx, hypopharynx, and esophagus. The narrow portions of the esophagus, where pooling of secretions can occur, are also commonly involved. Alkalis may also cause gastric necrosis (Figs. 148.1 and 148.2), intestinal necrosis, and perforation. The esophagus can also be injured (Fig. 148.3). Burns below the

Caustic injury is categorized as first, second, and third degree, similar to a thermal burn, by appearance on endoscopy. The initial depth of injury found on esophagoscopy correlates with the risk of stricture formation. Grade I injury consists of edema and hyperemia. Grade II injury can be further divided into grade IIa, which is non-circumferential, and grade IIb, which is nearly circumferential. Overall, grade II injuries are characterized by superficial ulcers, whitish membranes, exudates, friability, and hemorrhage. Grade III injury is associated with transmural involvement with deep injury, necrotic mucosa, or frank perforation of the stomach or esophagus. Although grade I injuries do not progress to stricture, 15% to 30% of all grade IIa injuries and up to 75% of circumferential grade IIb injuries of the esophagus develop strictures. With grade III injury, up to 90% result in pylorus carry a 50% mortality compared with 9% for burns above the pylorus.

Caustic damage occurs in four phases. Initially, necrosis occurs, with invasion by bacteria and polymorphonuclear leukocytes. Vascular thrombosis follows, increasing the damage. During the next 2 to 5 days, superficial layers of injured tissue begin to slough. The tensile strength of the healing tissue may be low for up to 3 weeks after the caustic exposure, greatly increasing the chance of delayed perforation in some cases. Between 1 week and several months, granulation tissue forms, collagen is deposited, and reepithelialization occurs in the burn area. Esophageal stricture may form during a period of weeks to years from contraction of the scar.

With grade III injury, up to 90% result in pylorus carry a 50% mortality compared with 9% for burns above the pylorus.
Airway edema and esophageal or gastric perforations are the most emergent issues. Laryngeal edema begins in minutes and occurs over several hours. Systemic toxicity, hypovolemic shock, and hemodynamic instability with hypotension, tachycardia, fever, and acidosis are ominous signs. Small ingestions of potent substances can be as serious as larger ingestions. More than 40% of patients reporting to have “only taken a lick or sip” have esophageal burns. Patients with acid or alkali ingestions present with similar initial constellation of signs and symptoms. Oral pain, abdominal pain, vomiting, and drooling are common. Patients can have wheezing and coughing, respiratory distress, hoarseness, odynophagia, dysphagia, stridor, and dysphonia. Chest pain is common. Visible burns to the face, lips, and oral cavity may be seen (Fig. 148.4), although these signs are not always clinically reliable.5,6 Skin burns can occur from spillage or secondary contamination after vomiting. Peritoneal signs suggest hollow viscus perforation or contiguous extension of the burn injury to adjoining visceral areas. Tracheal necrosis is one of the most frequent causes of death after caustic ingestion.

Oropharyngeal burns alone are not predictive of more distal injury, but drooling, odynophagia dysphagia, vomiting, and stridor, especially in combination, are highly predictive of significant lesions.

Dysphagia usually subsides in 3 to 4 days. Patients with significant esophageal burns, particularly those that are circumferential, may develop esophageal stricture; 80% of strictures become apparent in 2 to 8 weeks. Symptoms include dysphagia and food impactions. Strictures that become symptomatic early are generally more severe. In one study of 86 adults admitted to the hospital after caustic ingestion, 18 had complications with strictures and six died.

Patients with significant esophageal injury have a thousand-fold increase in esophageal carcinoma, which develops 40 to 50 years after the caustic ingestion. Long-term, 2% of patients who ingest caustics develop esophageal cancer and nearly 3% of patients reporting to have “only taken a lick or sip” have esophageal burns. Patients with acid or alkali ingestions present with similar initial constellation of signs and symptoms. Oral pain, abdominal pain, vomiting, and drooling are common. Patients can have wheezing and coughing, respiratory distress, hoarseness, odynophagia, dysphagia, stridor, and dysphonia. Chest pain is common. Visible burns to the face, lips, and oral cavity may be seen (Fig. 148.4), although these signs are not always clinically reliable.5,6 Skin burns can occur from spillage or secondary contamination after vomiting. Peritoneal signs suggest hollow viscus perforation or contiguous extension of the burn injury to adjoining visceral areas. Tracheal necrosis is one of the most frequent causes of death after caustic ingestion.

Oropharyngeal burns alone are not predictive of more distal injury, but drooling, odynophagia dysphagia, vomiting, and stridor, especially in combination, are highly predictive of significant lesions.

Dysphagia usually subsides in 3 to 4 days. Patients with significant esophageal burns, particularly those that are circumferential, may develop esophageal stricture; 80% of strictures become apparent in 2 to 8 weeks. Symptoms include dysphagia and food impactions. Strictures that become symptomatic early are generally more severe. In one study of 86 adults admitted to the hospital after caustic ingestion, 18 had complications with strictures and six died.

Patients with significant esophageal injury have a thousand-fold increase in esophageal carcinoma, which develops 40 to 50 years after the caustic ingestion. Long-term, 2% of patients who ingest caustics develop esophageal cancer and nearly 3% of esophageal cancer patients have a history of caustic ingestion.

Significant acid ingestions may be devastating and result in a higher mortality rate than alkali ingestions. The fulminant course of some acid ingestions may be due to systemic absorption of the acid, resulting in metabolic acidosis (which may also be the result of extensive tissue necrosis), hemolysis, and renal failure. Ingestion of glacial acetic acid (80% acetic acid) is common among certain ethnic populations as a suicidal gesture or accidental ingestion during food preparation, resulting in systemic complications, including renal and hepatic insufficiency, hemolysis, and disseminated intravascular coagulation. Ingestion of H₂SO₄ and HCl typically does not cause these systemic complications.

On clinical evaluation, the goal is to identify the extent and severity of the burn. In evaluation of a patient, the history should include the time, amount, type of product ingested, and presence of suicidal intent, if any. Patients who are suicidal may minimize their symptoms or underestimate the trauma. Physical examination addresses all of the above described features, so it focuses particularly on the oropharynx, supraglottic area, airway, and gastrointestinal (GI) tract.

**DIFFERENTIAL DIAGNOSES**

The ingestion of a caustic agent is usually clinically apparent upon presentation, most often by patient or family member report. When this is not known, the differential diagnosis is essentially that of abdominal discomfort, nausea, and vomiting, until typical mucosal injury becomes apparent. Mucosal injuries can be the result of various causes. The presence of early shock or altered mental status soon after ingestion of a caustic agent should prompt the search for other causes. Gastroenteritis from the ingestion of heavy metals (eg, iron, arsenic) and hydrocarbons can result in similar clinical effects as seen in caustic ingestions. Other GI conditions such as gastric perforation, esophageal rupture, esophagitis, and gastroesophageal reflux disease should be considered. Patients suffering from allergic reactions progressing to anaphylaxis can present with irritation and inflammation of the throat and larynx mimicking a caustic ingestion. Infectious sources such as aspiration pneumonitis, croup (laryngotracheobronchitis), and epiglottitis can present in a similar manner as well.

**DIAGNOSTIC TESTING**

Product labels are important in confirming the concentration of the chemical. If a sample is obtained, call the poison center for product information, look up the contents, or test the pH with litmus paper.

Evaluation of the severity of caustic ingestion and determination of the likelihood of deterioration or serious injury is based on examination of the upper airway, the esophagus, and the chest and abdomen. Examination of the oral pharynx is by direct visualization. Nasopharyngoscopy, after appropriate application of a vasoconstrictor (eg, Neo-Synephrine) and local anesthesia (eg, 4% lidocaine), determines the extent of injury and edema posterior to the tongue and in the supraglottic area and the glottis itself. Flexible endoscopy is used to evaluate the esophagus and stomach, after completion of the airway evaluation. Computed tomography (CT) scan is much more accurate than plain radiography for identification of perforation of the GI tract, and both chest and abdomen are scanned when there is concern for serious injury (see earlier criteria). CT of the chest and the abdomen are able to detect evidence of perforation, such as mediastinal and extraluminal air with high sensitivity.7,8 Another benefit to CT is the ability to evaluate tissues unable to be directly visualized during endoscopy due to technical challenges or safety.7,8 Although chest and abdominal radiography are often used in the early stages to determine whether perforation has occurred, they are insensitive and these tests are not indicated if CT scan is contemplated.

Patients with significant injury (such as grades IIb or III) may have perforations difficult to detect during endoscopic evaluation. Thus, delayed (approximately 24 hours post ingestion) esophagram with water soluble contrast medium may detect perforations by the presence of extravasation of contrast. If there is a high clinical suspicion, we recommend barium in the case of
a non-diagnostic water soluble contrast study that does not demonstrate leak because barium is more radiopaque. Esophageal dilation, widening of the pleuroesophageal line, and pleural reflection displacement all portend impending perforation.

Laboratory studies should evaluate for acidosis, coagulation profile, hemoglobin, and electrolyte derangement. Some ingested acids are absorbed from the gastric mucosa and subsequently hydrogen ion disassociation occurs. The accumulation of the anionic species in the vascular space contributes to an elevation in ion gap. Ingestion of acids such as HCl result in a non-anion gap metabolic acidoses because both the dissociated hydrogen and chloride ions contribute in the measurement of the anion gap. Typically, alkalis are not absorbed from the gastric mucosa into the vascular space. A lactic acidoses can result, however, due to esophageal or gastric injury and necrosis. Therefore, in the setting of significant acid or alkali ingestion, serum pH and chemistry for serum bicarbonate analysis are indicated to determine the degree of acidosis. In cases of intentional overdose, co-ingestants should be considered and measured diagnostically if levels are available and clinically indicated.

Hydrofluoric acid exposures, whether by inhalation, ingestion, or dermal contact (hand size or larger), are notorious for the effect of absorbed fluoride, resulting in hypocalcemia, and require immediate cardiac monitoring to assess for corrected QT (QTc) prolongation, torsades de pointes, or other ventricular dysrhythmias. Rapid cardiac deterioration can occur in these cases. Serum calcium, potassium, and magnesium levels should also be determined in these cases.

The depth and extent of injury cannot be predicted based on signs and symptoms alone. Patients with signs and symptoms (vomiting, drooling, stridor, or dyspnea) of intentional ingestion should undergo endoscopy within 12 to 24 hours to define the extent of the disease. Endoscopy is contraindicated, however, in patients with likely or known perforation. Endoscopy performed too early may miss the extent or depth of tissue injury. Wound softening in the subacute phase when the likelihood of perforation is greatest makes late endoscopy (after 24 hours) more hazardous. Wound strength is weakest between day 5 to day 14 and the time of greatest risk for perforation. Early endoscopy has been studied and shown to be beneficial to patients. Early endoscopy and GI tract evaluation permits more rapid administration of nutritional support. However, the endoscopy should terminate at the level of the most proximal circumferential burn, particularly if the burn is severe, to avoid iatrogenic perforation. A soft feeding tube or silk string can be placed in the esophagus, when burns are present, for future dilation.

**MANAGEMENT**

Early and continuous hemodynamic monitoring is indicated. All contaminated clothing should be removed to prevent ongoing injury to the patient as well protection of healthcare care personnel. Appropriate personal protective equipment and hazardous waste disposal should be used.

After a caustic ingestion, little can be done to attenuate the severity of the tissue injury. Early endotracheal intubation or upper airway endoscopic examination is warranted when there are indications of upper airway injury on nasopharyngoscopy. If there are significant symptoms or signs, such as respiratory distress, stridor, or voice alteration (hoarseness, muffling), intubation is often necessary early in the course of evaluation, before edema and secretions both threaten the airway and make intubation difficult or impossible. For this reason, upper airway examination is often done with an intubating bronchoscope so that if significant injury and edema are identified, intubation can be accomplished during performance of the bronchoscopic examination. Blind nasotracheal intubation is contraindicated. When oral intubation is planned, a video laryngoscope should be used to provide optimal view with the least tissue trauma. If significant symptoms and signs are present, intubation can be anticipated to be difficult, and awake flexible endoscopy is the method of choice.

After the airway is secured, persistent hypoxia and an increasing arterial-alveolar gradient warrant early bronchoscopy. Patients should have intravenous fluid resuscitation (20 to 40 cc/kg 0.9 normal saline bolus). Oropharyngeal and GI injury secondary to caustic ingestion can result hypotension because of fluid shift from the intravascular to the interstitial space. Intravenous access should be established and a bolus of 20 mL/kg of isotonic crystalloid, usually normal saline, should be administered. Standard measures of resuscitative progress such as heart rate and urine output should be followed closely. In alert patients who are not vomiting and can tolerate liquids, small volumes (1 to 2 cups) of water or milk can be considered within the first 5 minutes after ingestion. Because injuries occur almost immediately, later dilution is not warranted. Forcing of fluids is never indicated.Attempts to neutralize the ingested corrosive with weak acids or alkalis can cause possible thermal reactions and worsen the injury.

GI decontamination after caustic ingestion is generally not indicated and can be hazardous. Inducing emesis is absolutely contraindicated given the risk of re-induction of the caustic agent into the esophagus, oropharynx, and airway. Activated charcoal is contraindicated as well, because it has little effect and will interfere with the endoscopist’s view.

Careful nasogastric aspiration may decrease the amount of acid absorbed and may be useful in the setting of significant (massive) acid ingestions presenting 30 to 45 minutes after the event, given the ominous natural history of many of these cases and the lower risk of esophageal perforation compared with alkali ingestion.

Surgical consultation is indicated for free air, peritonitis, increasing and severe chest and abdominal pain, and hypotension.

Corticosteroid treatment does not significantly decrease stenosis after grade IIa, IIb, or III esophageal burns, and it may increase risk for hemorrhage, infectious complications, severe esophagogastric necrosis, and prepyloric ulcer formation. Steroids can also mask early signs of inflammation and inhibit resistance to infection. Accordingly, they are not indicated to reduce the extent of esophageal injury. Controversy also surrounds the administration of steroids in patients with airway edema secondary to caustic ingestion. There are no controlled studies evaluating this practice, and the same downside risks exist as for steroid use for esophageal stricture. Airway edema can be fatal, however, and a single dose of a potent corticosteroid might mitigate some of the edema with minimal risk for the patient. We recommend 10 mg IV dexamethasone when there is indication of airway edema.

Prophylactic antibiotics are not indicated. Patients with proven perforation should have an emergent surgical consultation.

**DISPOSITION**

Asymptomatic patients can undergo endoscopy in the emergency department. Those patients with grades 0 or 1 injury may be discharged home with close follow-up monitoring with appropriate gastroenterology or otolaryngology consultants. They can have a liquid diet for 24 hours and then progress to soft food over the next 3 days and to full diet thereafter if all goes well.

Surgical intervention is required in cases of hollow viscus perforation; early exploration may also be warranted in cases of suggested full-thickness burns. Symptomatic patients, particularly those with potential for airway compromise, or high-grade esophageal or gastric injuries require admission to the intensive care unit. If endoscopy is unavailable, the patient should be
SPECIAL CASES

Ocular alkali exposures are true ophthalmologic emergencies. Immediate irrigation with at least 2 L of normal saline per eye is indicated in almost all cases except frank perforation. Management is described in Chapter 61.

Dermal caustic exposures can also result in significant burn injuries (see Chapter 57). Clothing removal, copious irrigation, and local wound débridement are the most important initial treatment measures.

Povidone-Iodine

Povidone-iodine (Betadine) is used as a surgical scrub and is not a caustic agent, but ingestion of tincture of iodine can cause severe GI injury and is potentially life-threatening. Gastric irrigation with starch or milk in these cases may convert iodine to the much less toxic iodide. Either of these agents is most likely to be effective if administered within the first 30 to 45 minutes post ingestion. The goal is turning the gastric effluent dark blue or purple.

Phenol and Formaldehyde

Ingestion of phenol or formaldehyde can also cause severe caustic injury to the GI tract. Both phenol and formaldehyde are general protoplasmic poisons and can cause protein denaturation and coagulation necrosis. Systemic symptoms, including dysrhythmias, hypotension, seizures, and coma, may also result from phenol ingestion. Acidosis may be prominent after formaldehyde ingestion because of its metabolism to formic acid. Phenol is well absorbed through the skin, and dermal exposure may result in burns and systemic toxicity. Although dermal decontamination of phenol exposures with low–molecular-weight polyethylene glycol has been suggested, there is no evidence that it is superior to irrigation with water, which is more readily accessible.

Hydrogen Peroxide

Ingestion of concentrated (industrial strength) hydrogen peroxide (H₂O₂) may cause GI burn injury and the formation of gas emboli. Radiographic evaluation for the presence of gas in the chest or abdominal cavities, including the portal system, should be performed in symptomatic patients or those who ingest concentrated H₂O₂. Hyperbaric oxygen has been used successfully to treat gas emboli from H₂O₂ ingestion.

Button Batteries

Button (disk) batteries and conventional alkaline cylindrical batteries pose potential obstructive and chemical hazards if they are ingested. Ingestion of large 25-mm wafer-sized button batteries was a common problem in the past, but the smaller button batteries of today are less likely to cause esophageal obstruction. Button batteries are usually made of a metallic salt (lithium, mercury, nickel, zinc, cadmium, or silver) bathed in NaOH or KOH. Obstruction can cause pressure necrosis, caustic injury due to leakage of alkaline medium, or electrical injury. Caustic injury is much less common. Ulceration, perforation, and possible fistula formation occur but are uncommon. Heavy-metal toxicity in this setting has not been reported with newer disk batteries.

Evaluation of button battery ingestions includes radiography to assess the position of the foreign body. Batteries lodged in the airway or esophagus require expeditious removal. Gastric or intestinal batteries can be treated with watchful waiting. Checking the stool for passage of the batteries is recommended. Follow-up radiographs should be obtained in 1 week if the battery has not passed. If the patient becomes symptomatic with acute abdominal pain or exhibits GI bleeding, expedited reassessment is indicated.

KEY CONCEPTS

- Health care workers caring for patients with caustic exposures should adhere to universal precautions to prevent additional exposure.
- All symptomatic patients should undergo endoscopy and be considered for admission.
- Asymptomatic patients can undergo endoscopy in the emergency department or be discharged with close follow-up monitoring.
- Gastric emptying or GI decontamination is not indicated for the majority of caustic ingestions.
- Concentration and pH are the most important characteristics of a substance to predict esophageal and gastric injury.
- Button batteries lodged in the airway or esophagus require endoscopic retrieval.

CHAPTER 148: QUESTIONS & ANSWERS

148.1. A patient presents after the intentional ingestion of hydrochloric acid (HCl). He complains of mouth, throat, and chest pain, as well as painful swallowing and nausea. His vital signs are normal. Physical examination reveals oral burns without edema. The remainder of the examination is normal. You decide that in addition to psychiatric consultation, the patient should have upper endoscopy. What is the best time for the patient to have the endoscopy?
A. Immediately
B. In 2 to 4 hours
C. In 4 to 12 hours
D. In 12 to 24 hours
E. In 2 or 3 days

Answer: D. The ideal time for endoscopy is 12 to 24 hours. Endoscopy done too soon may miss the extent or depth of injury, whereas endoscopy after 24 hours is actually more likely to cause perforation because the wounds have softened. All patients with signs or symptoms of strong acid ingestion as well as patients with intentional ingestion should have endoscopy performed.

148.2. A patient presents immediately after the ingestion of bleach. The patient is awake and alert and complaining only of mouth pain. His vital signs and physical examination findings are normal. You consider having the patient drink fluids to dilute the bleach. Which of the following statements regarding this therapy is true?
A. Dilution is beneficial only if it is done very soon after ingestion.
B. In cases of alkali ingestions, dilution with a mild acid such as acetic acid is best.
C. Large volumes of fluid should be used.
D. Milk should always be used instead of water.
E. Patients should also be encouraged to eat solids.

Answer: A. Dilution, if it is done at all, should be done early because injuries from caustics occur almost immediately. Water and milk are equally beneficial and are the agents of choice. Weak acids or alkalis should never be used for dilution, because they can cause thermal reactions that worsen the injury. Small volumes up to approximately 500 mL should be used. Solids are not beneficial and can complicate the situation and increase the risk of aspiration.

148.3. A patient presents after an intentional caustic ingestion. She complains of hoarseness, with mouth, throat, and chest pain. Burns are present on her lips and oral mucosa and she is drooling. Her vital signs are normal, as is the remainder of her physical examination. Which of the following is the most appropriate treatment?
A. Administer 500 mL water orally
B. Administer intravenous Solu-Medrol
C. Endotracheal intubation
D. Obtain electrocardiogram
E. Upper endoscopy

Answer: E. Early intubation is indicated if there is any evidence of airway compromise, such as hoarseness, throat pain, drooling, or edema. Because edema and secretions can both increase rapidly and can make intubation difficult or even impossible, preparations should be made for a difficult airway. Fluids for oral dilution should not be given if the patient has difficulty swallowing. Corticosteroids have been studied to decrease the incidence of stricture formation, but evidence for their benefit is lacking and serious side effects can occur. With the exception of hydrofluoric acid, an electrocardiogram is not routinely needed for caustic ingestions, and endoscopy should be performed 12 to 24 hours after the ingestion and after the airway has been secured.

148.4. What empirical treatment is indicated to prevent systemic toxicity from hydrofluoric acid ingestions?
A. Calcium chloride
B. Magnesium chloride
C. Potassium chloride
D. Sodium bicarbonate
E. Sodium chloride

Answer: A. Calcium chloride is indicated in significant hydrofluoric acid exposures. Although hydrofluoric acid is a weak acid, the fluoride ion is extremely electronegative and will bind with multiple cations, specifically calcium and magnesium. Profound hypocalcemia is responsible for most deaths from hydrofluoric acid exposure and can occur before a serum calcium concentration can be measured.

148.5. A 3-year-old boy presents after swallowing a button battery. What is the most appropriate management?
A. Endoscopic removal
B. Inpatient observation
C. Radiograph to assess anatomic location
D. Surgical removal
E. Whole-bowel irrigation

Answer: C. Outpatient observation is warranted for button batteries that are located in the stomach or intestines, which can be assessed by plain radiographs. Batteries lodged in the esophagus require endoscopic removal. Examination of the stool for passage of the battery is recommended. If it is not passed in 1 week, repeated radiographs should be obtained. Inpatient observation is not needed as long as close follow-up can be ensured. Surgical removal and whole-bowel irrigation are not beneficial and are potentially deleterious.
CHAPTER 149

Cocaine and Other Sympathomimetics

Rama B. Rao | Robert S. Hoffman | Timothy B. Erickson

PRINCIPLES OF TOXICITY

Cocaine, amphetamines, and derivatives of amphetamines are called sympathomimetics (Box 149.1). These agents cause central nervous system (CNS) stimulation and a cascade of adrenergic physiologic effects. Cocaine is a naturally occurring plant-derived alkaloid that has been used for centuries as a medicinal product. In 1860, the pure alkaloid form was isolated and became a popular constituent of various beverages, pharmaceuticals, and therapeutic tonics, but it was banned from these products in the United States in 1914. As of 2012, there are roughly 17 million users worldwide. Cocaine use in the United States peaked in the early 1990s at an estimated 5 million people with up to 1.6 million users of cocaine reported as of 2010. Cocaine accounts for 40% of drug misuse related deaths and up to 40% of United States emergency department (ED) visits for illicit drug use.

Amphetamines are stimulants originally designed for use as decongestants and dietary aids that became popular as recreational drugs in the mid-20th century. By modification of the amphetamine molecule, illicit “designer” amphetamines are inexpensive produced. The enhanced effects from these alterations add to the popularity of drugs, such as N-methyl-3,4-methylenedioxyamphetamine (MDMA) and methamphetamines. Estimates place the number of methamphetamine users in the United States at approximately 600,000.

Cocaine Formulations

Unpurified cocaine paste is converted to more usable forms of cocaine. The crystallized freebase of the cocaine alkaloid is known as crack cocaine. It is inhaled with use of a special “crack pipe” designed to tolerate the high temperature required to volatilize pure cocaine. The high lipid solubility and rapid transport from the lungs into the brain contribute to crack’s rapid onset of action (Table 149.1). The water-soluble salts of cocaine (cocaine hydrochloride and cocaine sulfate) are available as a white crystalline powder that is used intranasally or dissolved and injected intravenously. Oral administration is rare except for patients who are smuggling or concealing drugs.

Pathophysiology of Cocaine

Acute cocaine use causes release of dopamine, epinephrine, norepinephrine, and serotonin. These neurotransmitters act on different receptor subtypes to cause many effects, but the most important is adrenergic stimulation by norepinephrine and epinephrine (see Box 149.1). Norepinephrine causes vasoconstriction by stimulation of alpha-adrenergic receptors on vascular smooth muscle. Epinephrine increases myocardial contractility and heart rate through stimulation of beta-adrenergic receptors on the heart muscle. Epinephrine release (Fig. 149.1). Reuptake of serotonin is similarly inhibited and can cause serotonergic excess as well.

Cocaine also is a local anesthetic agent, slowing nerve impulses from neuronal pain fibers by blocking the inward movement of sodium across cell membranes (during phase 0 of the action potential). Sodium channel blockade across myocardial cells, similar to the class IA antidysrhythmics, is responsible for the occasional conduction abnormality that is noted in patients with acute cocaine toxicity.

Cocaine metabolism occurs in the liver and the plasma. In the liver, the drug is metabolized primarily to the active metabolite norcocaine, which potentiates the parent drug. In the plasma, cocaine is metabolized to ecgonine methyl ester through pseudocholinesterase (plasma cholinesterase). This difference may account for the differences in duration of action with different routes of administration. Ecgonine methyl ester may be protective because it is a vasodilator. Genetic differences in the phenotypic expression of plasma cholinesterases may account for individual differences in susceptibility to cocaine toxicity.

Benzoyl ecgonine, a metabolite found in the plasma, is produced primarily from nonenzymatic hydrolysis. It is the metabolite of cocaine identified by urine toxicology screens. Methylecgonidine and its metabolite ecgonidine are products of cocaine pyrolysis (crack). Although it is less commonly assayed, methylecgonidine also can be identified in the urine. The use of ethanol with cocaine forms cocaethylene, a metabolite that may potentiate the drug’s stimulatory effects and lengthens the duration of effect.

CLINICAL FEATURES

The primary clinical effect of cocaine is the excitation of the sympathetic nervous system. Patients with moderate toxicity are alert and awake but may have diaphoresis, tachycardia, mydriasis, and hypertension without organ damage. A more severely toxic patient may be agitated, combative, and hyperthermic. End-organ damage is rare but may be manifested as an acute hypertensive emergency. Patients may present with focal acute pain syndromes, circulatory abnormalities, delirium, or seizures.

The clinical presentation depends on the dose, route of administration, and time to presentation after drug use. Additives, contaminants, or other drugs may alter the classic signs of acute cocaine toxicity. Patients who are “speed balling,” using intravenous (IV) heroin and cocaine together, may be initially sedated, and administration of naloxone may precipitously reveal the underlying cocaine toxicity.

Death due to acute cocaine overdose is significantly higher on days with ambient temperatures higher than 88°F, possibly as a result of the individual’s impaired ability to cool in warmer temperatures. The profound diaphoresis associated with cocaine may be absent or limited in cooler environments or if the patient is excessively salt and water depletes.

Initial assessment should focus on rapidly fatal complications, specifically hyperthermia, hypertensive emergencies, and cardiac dysrhythmias.
Delay in recognition and management increases the likelihood of death. Even with a normal temperature, increased motor tone can release intramuscular (IM) creatine kinase (CK), with rhabdomyolysis and its attendant renal and electrolyte complications.

**Hypertensive Emergencies**

Acute cocaine-induced hypertension can cause serious injury to the cardiovascular and central nervous systems. Reported sequelae include aortic dissection, pulmonary edema, myocardial ischemia and infarction, intracranial hemorrhage, stroke, and infarction in the distribution of the anterior spinal artery. Vasospasm can also compromise perfusion to various organs. Intestinal infarctions and mesenteric ischemia can occur, particularly in body packers with large oral ingestions. Other local ischemic events include retinal vasospasm, renal infarctions, and placental insufficiency and infarction in the gravid uterus.

**Cardiac Dysrhythmias**

Although sinus tachycardia is the most common rhythm, atrial fibrillation and other supraventricular tachycardias can occur as a result of the surge in catecholamines. Life-threatening dysrhythmia may occur suddenly, heralded by abrupt diminution of cardiac output and loss of consciousness. Torsade de pointes from potassium channel blockade or wide-complex tachycardias from blockade of fast sodium channels on the myocardium may deteriorate into poorly perfusing or fatal ventricular rhythms. Transient conduction abnormalities consistent with a Brugada-type pattern are associated with cocaine. Hyperkalemia from rhabdomyolysis and myocardial ischemia can also cause dysrhythmias.

**Other Complications**

People who binge on repeated doses of cocaine for an extended time have a prolonged state of arousal, which causes catecholamine...
depletion, salt and water depletion, and poor nutrition. After the acute effects of cocaine have subsided, these patients with “cocaine washout” are profoundly sleepy but arousable and oriented, with normal vital signs or a mild sinus bradycardia.

Patients are occasionally noted to be “crack dancing,” which is defined as a transient choreoathetoid movement disorder probably related to abnormalities in dopaminergic tone.1 Paranoia, either drug induced or from underlying psychiatric illness, may occur even after the acute effects of the drug subside. The neuropsychiatric effects of cocaine can alter behavior and judgment, increasing the risk of violent injuries.

Complications also arise from the route of administration of cocaine. Inhalation of crack cocaine may cause oropharyngeal burns from the high temperature required to volatilize the drug. Pneumothorax, pneumomediastinum, and pneumomediastinum occur from inhalational barotrauma. Intranasal cocaine use is associated with sinusitis and nasopalatine necrosis or perforation. IV users have a high risk of infection with blood-borne viruses, local abscesses, and systemic bacterial infections, including botulism and endocarditis. Transdermal injection of cocaine, or “skin popping,” has similar types of complications, especially skin abscesses. For chronic users, addiction or psychological dependence is mediated through specific dopaminergic neurotransmitter pathways. Although there are no well-defined syndromes constituting cocaine withdrawal, patients have strong cravings for the drug or a general feeling of dysphoria that is not physiologically life-threatening.

Over the last 10 years levamisole, a veterinary anthelmintic drug, has been increasingly used as an adulterant of cocaine. Levamisole was used historically to treat pediatric nephritic syndrome and rheumatoid arthritis before being withdrawn from the market due to its significant toxicity (ie, hematological complications and vasculopathy).7 Agranulocytosis, vasculopathy with thrombosis, dermal ulcers, and purpura, often affecting the earlobes, occurred as a result of the unintentional exposure to levamisole.8-10 The reason for this adulteration of cocaine with levamisole is still not clear but likely continues.

### DIFFERENTIAL DIAGNOSES

A thorough assessment of mental status, vital signs, and physical examination can help direct and narrow the differential diagnosis of cocaine toxicity. History may be particularly helpful in differentiating acute cocaine toxicity from the many causes of agitated delirium, including thyrotoxicosis, lithium toxicity, other toxins, and CNS infection. Thought disorders and auditory hallucinations generally are not present, in distinction to acute psychosis from drug induced or from underlying psychiatric illness, may occur even after the acute effects of the drug subside. The neuropsychiatric effects of cocaine can alter behavior and judgment, increasing the risk of violent injuries.

Complications also arise from the route of administration of cocaine. Inhalation of crack cocaine may cause oropharyngeal burns from the high temperature required to volatilize the drug. Pneumothorax, pneumomediastinum, and pneumomediastinum occur from inhalational barotrauma. Intranasal cocaine use is associated with sinusitis and nasopalatine necrosis or perforation. IV users have a high risk of infection with blood-borne viruses, local abscesses, and systemic bacterial infections, including botulism and endocarditis. Transdermal injection of cocaine, or “skin popping,” has similar types of complications, especially skin abscesses. For chronic users, addiction or psychological dependence is mediated through specific dopaminergic neurotransmitter pathways. Although there are no well-defined syndromes constituting cocaine withdrawal, patients have strong cravings for the drug or a general feeling of dysphoria that is not physiologically life-threatening.

*CNS, Central nervous system; PCP, phencyclidine*
Unlike serotonin syndrome, peripheral muscular effects tend toward rigidity and decreased reflexes rather than clonus and hyperreflexia. This is due to dopaminergic depletion from the use of dopamine antagonists, such as the older or classic antipsychotic agents. Patients presenting with NMS generally have a gradual course of hypokinesis and increasing resting muscle tone in the setting of escalating antipsychotic use. The alteration in mental status is more commonly a catatonic state.

**DIAGNOSTIC TESTING**

Urine drug screening for cocaine is unlikely to change treatment, because it measures a cocaine metabolite (benzoyl cgonine) that persists for at least 3 days after last use. In a few circumstances, however, urine drug screening may be beneficial to document possible abuse or neglect in a child with suggested exposure, to confirm cocaine as the unknown substance in body packers, and to differentiate paranoia from drug-induced or psychiatric causes. Urine drug screening may be informative in the evaluation of younger patients with chest pain syndromes. Although sensitivities for amphetamines may vary, therapeutic agents may be detected and confound interpretation. Other potent adrenergic synthetic stimulants may be undetectable on urine drug screening.

An electrocardiogram (ECG) screens for dysrhythmias and conduction abnormalities from ischemia, hyperkalemia, or, more precipitously, QRS prolongation from sodium channel blockade. This blockade slows myocardial depolarization and results in a wide-complex tachycardia. The axis may be indeterminate or have a terminal rightward axis deviation similar to cyclic antidepressant toxicity. Cyclic antidepressants and cocaine share class IA antidysrythmic effects with QRS widening and resultant QT prolongation. Evaluation of chest pain is challenging, because ST segment elevation is confounded by the presence of early repolarization. Serial ECGs may be helpful and obtained with any change in status or every 6 hours during care. A chest radiograph may identify aspirated foreign bodies, pneumothorax, or pneumomediastinum from inhalational barotrauma, when these are suspected, but is not required in most cases.

CK, a nonspecific marker for muscle injury, is often elevated with cocaine use. The original data on cocaine related coronary syndromes used CK-MB as a cardiac marker; however, this is now supplanted by troponin I or troponin T levels, as for all patients evaluated for possible ischemic chest pain.

Most patients presenting with troponin elevation and chest pain after cocaine use had angiographically proven obstructive coronary disease, often of a single vessel, but almost 20% have normal angiography. Although the sensitivity and specificity of troponin cardiac markers are still being investigated for cocaine-related chest pain, we recommend that patients with cocaine use be evaluated for chest pain in a similar fashion to that for patients without cocaine use. Decisions regarding further investigation are based on the characteristics and course of the chest pain and results of serial troponin measurements and ECGs. Data regarding the role of coronary computed tomography angiography (CTA) to identify patients with cocaine-related coronary disease are evolving. We do not recommend routine use of CTA in the evaluation of patients with chest pain in the context of acute cocaine use.

Severe, persistent headache despite normalization of blood pressure may be caused by a subarachnoid hemorrhage (SAH) and warrants evaluation as for any other patient suspected of acute SAH (see Chapters 91 and 93). A serum CK and urine for myoglobin should be checked to screen for rhabdomyolysis.
